CONSERVATISM IN OBSTETRICS.*

BY EDWIN B. CRAGIN, M. D.,
New York.

The last few years have witnessed the development of radical surgical obstetrics and brilliant the results have been. Long lists of Cæsarean sections have been published with little if any mortality, and the indications for the operation have been extended by some to include placenta prævia, eclampsia, accidental hemorrhage, etc. The question before us is: Are we in our enthusiasm over radical obstetric surgery neglecting the fundamentals of obstetrics; the routine precautionary methods which may make the resort to radical obstetric surgery unnecessary? The consultant still sees cases of puerperal infection; of ruptured uteri; of undiagnosed posterior positions of the occiput. He sees cases in which forceps have been applied too early, cases in which version has been attempted too late. We can only conclude that, in spite of brilliant results along certain lines, the fundamentals of every day obstetrics are still neglected. It is freely admitted that pelvimetry does not always tell whether a child can be born through the natural passages or not. The angle of junction of lumbar spine and sacrum may be such as to prevent the entrance of the fetal head into the pelvis in spite of large pelvic measurements. The writer has several times been obliged to perform a Cæsarean section upon a woman whose pelvic measurements were justo major, and whose dystocia came as a surprise, demonstrated only by hours of test labor. On the other hand, careful pelvimetry tells a great deal, and if a careful pelvimetry of the inlet and the outlet of the pelvis is practised during pregnancy and especially if coupled with it there is a careful comparison of the size of the presenting part and the brim of the pelvis, the surprises will be few and the possibility of dystocia can usually be foretold and provided for. The mouldability of the head and the strength of the uterine contractions are always uncertain factors in the problem, but pelvimetry will usually tell us at least one factor in the problem and should never be neglected. Pelvimetry is a part of conservative obstetrics, as it will disclose a large percentage of cases in which delivery through the natural passages is impossible, and these are in the women who should not be allowed to lower their vitality or the vitality of the child by labor. Furthermore, it will disclose a certain percentage of cases in which, if premature labor is induced, delivery may be accomplished without resort to radical obstetric surgery, even if forceps or version is necessary.

The importance of uranalysis in the care of an obstetric case has long been recognized, but the importance of regular and frequent examinations seems to have been neglected by many. It is freely admitted that a fulminating case of eclampsia in which the urine was normal on ordinary examination a week before, will occasionally occur. This is exceptional, however, and the rule is that if the urine is examined every two weeks, danger signals will be disclosed long before the eclamptic seizure.

The value of taking the blood pressure of a pregnant patient has only recently been recognized, yet it is one of the best criteria of the condition of the woman and her avenues of elimination, and the obstetrician who omits it from his routine procedures in the care of his obstetric cases is not doing his duty. With the portable, relatively inexpensive sphygmomanometers on the market, there is little excuse for the neglect of the blood pressure, and the more we study results the more we become impressed with the fact that a pregnant patient with a blood pressure of 140 or over is usually suffering from a serious toxemia. The importance of taking the blood pressure at short intervals during pregnancy and the valuable information to be gained by seeing the patient, noting the presence or absence of edema, makes it necessary that she should visit her obstetrician frequently during pregnancy and that simply sending the urine is not sufficient.

Now let us come to the delivery itself. I am writing for general practitioners. What precautions are you taking against puerperal infection, still the nightmare of the lying-in chamber? Do you provide yourselves with a sterile gown and with sterile rubber gloves? The time has passed when it is safe for a man to deliver a woman without all the precautions which the laity recognize as important in safeguarding a woman against infection. The use of rubber gloves is one of the safeguards known to the laity, and if a physician has not worn sterile rubber gloves and happens to have a case of puerperal infection, his lot is certainly not a happy one,

*Read before the Eastern Medical Society of the City of New York, Friday evening, May 12, 1916.

as he has the support of neither the laity nor the profession. On the other hand, it is known to the profession, at least, that in spite of every precaution puerperal infection will occasionally occur, even in the best of hands. This means that if a physician has used every precaution known to science as essential in preventing infection and yet happens to have a case of it, the profession will stand by him, but without such precautions he deserves and receives support from neither the laity nor the profession. Let me say, that it pays to be charitable toward any careful man who is unfortunate enough to have in his practice a case of puerperal infection. To criticise is easy, but alas! the tables may soon be turned and we may be the next unfortunate to spend anxious days and sleepless nights over a case of puerperal infection which came we know not how. There is only one redeeming light on the horizon of darkness. If we have used every precaution known to science, our conscience is clear, even if we are criticised by our fellow practitioners and by the laity. With any important precaution omitted even our conscience upbraids us, and this may be harder to bear than all other criticism.

Conservatism, as the writer uses the word, does not mean opposition to progress. It is used more in the sense of favoring progress which is not too rapid, progress which conserves the well being of both mother and child. We may well ask ourselves the question, Am I doing my obstetric work in the way that will best conserve the life and health of my two patients, the mother and the child? Thus far we have considered chiefly the mother, but the child certainly deserves consideration. Are we watching the fetal heart as we should? or are we taking it for granted that because we heard it once it will still be beating when the child is born? I know of no criterion of the well being of the child which compares to the rapidity and character of the fetal heart sounds, and no obstetrician seems to me to be doing his duty to the incoming member of society who does not keep posted as to the fetal condition by listening frequently to the fetal heart during labor. It may be argued that after the obstetrician has put on his rubber gloves, he cannot listen to the fetal heart without unsterilizing them. This argument does not hold, as for years the writer has been in the habit of lifting with his gloved hands the sterile towel from the patient's abdomen and having the nurse pull down the night dress so that through it he could listen to the fetal heart; the night dress is then drawn up by the nurse, the towel which has been held with sterile hands is then replaced on the abdomen, and this process is repeated as often as may be necessary.

A few months ago the writer was summoned in the afternoon to one of the suburbs of the city to deliver a woman by forceps. One of my first questions was, Is the case ready for forceps delivery? The answer was, Oh, yes. It is time she was delivered. I made a hurried twenty-five mile run to the place in an automobile and on arriving and examining the patient found a cervical dilatation about the size of a silver quarter. I was obliged to tell the attending physician that I thought by next morning the cervix would be sufficiently dilated and the head sufficiently descended to make the forceps justifiable. I then returned to the city.

My object in mentioning this case is to call attention to the fact well known in most maternity hospitals in the city, that many cases are brought to our hospitals with the history that the doctor had applied the forceps and after several attempts had failed to deliver the woman. Many of these cases have shown, even on arriving at the hospital, a cervix without sufficient dilatation to make the use of the forceps justifiable.

There is a Scylla and a Charybdis in the use of the forceps in obstetrics. We might call the Scylla the too early application of the instrument, before the cervix is sufficiently dilated, and the Charybdis the too late application, after the fetal head has rested so long on the pelvic floor as to cause cerebral injury on the one hand and loss of vitality in the maternal soft parts on the other. Conservative obstetrics steers midway between the two, and this middle course is usually charted by a vaginal examination of the cervix and by careful and frequent listening to the fetal heart. The difference in the ease of delivery in an anterior and a posterior position of the occiput is so marked that the conservation of both mother and child depends largely upon the accurate diagnosis of the position of a vertex presentation. The consultant is not infrequently called to a case of persistent occiput posterior which undiagnosed has been left in ineffectual labor for twenty-four hours with perhaps repeated attempts to deliver with forceps, under the supposition that the posterior fontanelle was anterior. A correct diagnosis many hours before, with a manual rotation of the head till the occiput lay in front of the transverse diameter of the pelvis, and then the proper application of the forceps would have saved the mother many hours of exhausting labor and the child many hours of dangerous cerebral compression. The writer's plea is for early diagnosis of occipitoposterior positions, and as elements in this diagnosis he would emphasize:

1. The absence of the smooth broad fetal back from the front of the mother's abdomen.

2. The location of the greatest intensity of the fetal heart sounds outside of the line joining umbilicus and either anterior superior iliac spine.

3. The character of the labor pains.

This characteristic of labor in a persistent occiput posterior should be well known by all. The absence of flexion prevents ready descent of the vertex into the cervical canal with its associated stimulus to uterine contractions. This means that the uterine contractions are often feeble, far apart, and ineffectual. This type of labor—long, tedious, with little advance of the presenting part—is so often found associated with a persistent occiput posterior that this diagnosis should at least be suggested and should be either verified or excluded by careful examination.

There is one danger which is still not sufficiently understood by the general practitioner—version in a tonic uterus. If we have tried a forceps delivery in a given case and have failed, either on account of a disproportion between the presenting part and the parturient canal, or because on account of a poor

application of the forceps blades the instrument has slipped, it is only human to be tempted to try a version. The bimastoid diameter is shorter than the biparietal, and by a podalic version the smaller end of the wedge would be made to enter the pelvis first. Under certain conditions this would be good conservative obstetrics, but it all depends upon whether version is, or is not contraindicated by a tonic uterus. Version in a tonic uterus, with uterus contracted on the child and lower uterine segment thinned out, usually means rupture of the uterus and death of the mother in over seventy-five per cent. of cases. Certainly a craniotomy is better than a ruptured uterus.

With the present popularity of Cæsarean section and its low mortality—in the writer's last seventy-three cases there was only one death and that from an embolus in the course of a complicating bronchopneumonia and in the sixty-one cases just preceding this one there had been no death—we naturally ask the question, What is a conservative position to take regarding Cæsarean section?

The writer regards Cæsarean section as a conservative procedure when delivery of a living child through the natural passage is shown to be impossible, either from a contraction of the pelvis which makes the indication positive, or as the result of a test labor, *provided that certain conditions are present.* These conditions are:

1. Labor of short duration or not begun.

2. Unruptured membranes; or membranes only recently ruptured.

3. No recent vaginal examinations, or only one or two under strictest aseptic precautions with sterile gloved hands, etc.

If the woman has been a long time in labor with membranes ruptured many hours, the mortality of from two to three per cent. rises to a mortality of from ten to fifteen per cent., and the operation ceases to be a conservative procedure and becomes one of considerable hazard. This emphasizes the importance of an early diagnosis in all cases with a positive indication for Cæsarean section so that the operation can be performed either just before or in the early stages of labor. Moreover, it demonstrates the importance of the greatest care during the test labor of the border line cases in primigravidæ, that the labor should not be too long and that the vaginal examinations should be as few as possible and made with the strictest asepsis.

In conclusion, the writer would like to state his views of conservatism in the extension of Cæsarean section to conditions other than dystocia from pelvic contraction or tumors; for instance, placenta prævia, eclampsia, accidental hemorrhage, etc.

In the writer's judgment these conditions furnish an indication for a section only as a rare exception. In certain cases of complete placenta prævia with marked loss of blood and cervix not easily dilatable, a section offers the best prospect to mother and child. The same may be said of certain cases of accidental hemorrhage with complete premature separation of the placenta, but it is the writer's custom to deliver most of these women in some other way, usually after preliminary dilatation with the elastic bag.

One thing must always be borne in mind, viz., that no matter how carefully a uterine incision is sutured, we can never be certain that the cicatrized uterine wall will stand a subsequent pregnancy and labor without rupture. This means that the usual rule is, *once a Cæsarean always a Cæsarean.* Many exceptions occur, and recently one of my hospital patients upon whom I performed a section for an ovarian cyst, removing the cyst at the same time, came to me to report that she had since had three children without difficulty. In this case the obstruction had been removed and the labors were easy. The general rule holds, however, that we cannot depend on a sutured uterine wall, whether it is done in a Cæsarean section or a myomectomy, hence I believe that the extension of Cæsarean section to conditions other than dystocia from contracted pelvis or tumors should be exceptional and infrequent.

BONE SARCOMA TREATED BY RADIUM.*

By Joseph B. Bissell, M. D.,
New York.

These patients are presented as examples of results which sometimes follow the application of radium to sarcomatous tumors of the long bones.

Case I. W. T., nineteen years old, had been in several hospitals and clinics and under various treatments before coming under my care. He first noticed this growth nearly two years ago. He had had experience with considerable doses of x ray as well as Coley's serum. Two pathologists had reported upon specimens taken from the tumor. They concurred that it was an osteosarcoma of the spindle cell variety, arising from the periosteum. According to the skiagraph the growth involved the whole circumference of the left femur at its middle third. The early pictures before treatment with radium presented the characteristics of a sarcoma. The last picture, taken since the application of radium, is reported by Doctor Meyer, of Bellevue Hospital's x ray staff, to resemble a chronic periostitis. The patient had in addition a severe radium burn on the limb, extending deeply into the muscle of the inner side. This burn extended almost completely around the leg. It had taken a long time to heal and was still troublesome. Considering, however, that the tumor had practically disappeared under treatment, the patient was not making more than

Fig. 1.—Skiagraph of femur, W. T., taken November 1, 1915, before using radium.

*Patients and photographs presented before the Surgical Section, Academy of Medicine, May 5, 1916.

FIG. 2.—Skiagraph of femur, W. T., taken April 10, 1916, after using radium.

the ordinary complaints about the inconvenience of the condition. At the beginning of the radium treatment, the circumference of the leg over its largest point was 53.25 cm., the right leg at the same point being thirty-five cm. for contrast. The affected leg over the site of the original tumor is now 40.25 cm. in circumference, and part of this measurement is probably due to the swelling of the soft parts from the radium burn. This boy had rather large doses of radium, and for a comparatively long time. The average amount used was about 400 mgm., and for the first four or five times the exposure was twenty-four hours in length each time. Various kinds of screens were used and every endeavor was made to protect the skin from burns. There was a space screen of an inch and a half from his skin to the material screens, which consisted of from three to five mm. of rubber, and two mm. of brass or lead, depending upon the special applicator used, beside the original silver container, one mgm. in thickness, and the glass tube containing the radium.

The accompanying photographs show the improvement from the time he came under my care up to the present, when the last photograph. (Fig. 4) was taken. The skiagraph shows the improvement in the condition of the bone between the same dates.

FIG. 3.—W. T., aged nineteen years, photograph taken November 1, 1915, before using radium.

The second case is that of a small child, who at present is incarcerated in the isolation ward of the Willard Parker Hospital, suffering from a contagious disease.

CASE II. Isador S., five years old, first noticed a tumor in the upper third of the left humerus about a year ago. X ray pictures, soon after, showed evidences of a rarefied swelling of the bone. Later on this was seen to be a sarcomatous infiltration, subperiosteal in origin. The diagnosis was confirmed by the examination of a section by the pathologist. The following measurements were made in May, 1915, before applying the radium treatment: Over the greatest size of the tumor, twenty-two cm.; at its lowest portion, seventeen cm.; one inch above the greatest diameter, eighteen cm. Fifty mgm. of radium were applied around the bone in five containers of ten mgm. each. They were applied at equal distance points and remained on about two hours. They were applied close to the skin with three mm. lead screens covered with 0.5 mm. rubber. In a week's time this application was repeated, also two weeks later. The measurements taken early in July after these three applications were as follows: Over greatest diameter, eighteen cm., below fifteen cm., and above sixteen cm. Nothing more was done until the following September, when two similar applications were made, two weeks apart; the patient in the meantime continuing to improve until at this time there was very little difference between the arms. The child's general health was good. He had no pain or trouble of any kind relating to this tumor. Following the foregoing treatments there were no radium burns and the tumor almost disappeared. Palpation of the arm at the site of the tumor showed that there remained several irregular ridges parallel with the long axis of the bone. Late in November the tumor began to grow again; the patient's general condition became affected; he had slight chills, rise of temperature, loss of appetite, complained of pains in his arms and chest, and seemed otherwise ill. An x ray picture of his chest showed what was thought to be metastatic deposits in the mediastinum. In order that he might get the benefit of further radium applications, he was taken into the Radium Sanitarium and one hundred and fifty mgm.

FIG. 4.—W. T.; photograph taken May 5, 1916, after using radium. Ignore the skin burn which has now practically healed.

FIG. 5.—I. S., aged five years; photograph taken May 20, 1915, before using radium.

of radium was applied to his arm for twelve hours. Preceding this, a section was taken of the tumor, the pathologist reporting that it was a spindle cell sarcoma. A second x ray interpretation showed it to be subperiosteal. Another skiagraph, several weeks later, showed no such pathological condition in the chest as described above.

The tumor is still rather marked, although somewhat smaller than when the patient first came to the hospital. Several applications of radium of 150 mgm. each, for twelve or fourteen hours at a time, have not decreased it very much. He has a pronounced necrosis about an inch in diameter, of the soft parts of the arm, due to an x ray burn. His general health at present appears to be about normal.

FIG. 6.—I. S., aged five years; photograph taken August 20, 1915, after using radium.

These two patients are taken for contrast. One has apparently entirely recovered from the growth, the other has improved but slightly. The pathological condition, the character and position of the tumors, as well as the treatment carried out, are similar, yet the results are apparently opposite; although it must be said for the little boy five years old, that under a former series of radium applications the tumor had also practically disappeared. . In spite of this seemingly poor result I believe that radium properly applied is the correct treatment. The only alternative is amputation at the shoulder joint, with almost certain early return of the tumor, either in the scar or in some other part of the body.

At the Radium Sanitarium and laboratories we are constantly learning more about the pathological, histological, chemical, and clinical results of the action of radium and other agents upon the various malignant tumors in the human body. In some of its aspects malignant disease seems general or constitutional rather than local. It would not be surprising if in a short time such a theory proved to be a fact, and new growths, now regarded as limited, surgically removable, and curable, were recognized, after all, as only symptoms or indications of a widely disseminated dyscrasia not permanently eradicable by the knife alone.

46 WEST FIFTY-FIFTH STREET.

Congenital Elevation of the Scapula.—Samuel Cohen (*Medical Record*, June 10, 1916) describes a case of a boy of fourteen years whose left scapula was four cm. higher than his right. In addition, there was distinct cranial asymmetry, torticollis, displacement upward of the left nipple, scoliosis in the upper dorsal region away from the deformed scapula and elevation of the ribs on the affected side.

STRICTURE OF THE URETER.*

Excluding Tuberculosis and Calculus; Report of Fifty Cases,

BY GUY L. HUNNER, M. D.,
Baltimore, Md.
Associate in Clinical Gynecology, Johns Hopkins University.

Stricture of the ureter is a far more common disease than our former experience or a review of the literature would lead us to believe. Excluding tuberculosis stricture and infiltrations immediately surrounding stone in the ureter, I have records up to November 1, 1915, of fifty cases. In the same period I have treated forty-nine cases of tuberculosis of the urinary tract and thirty-nine cases of stone in the ureter.

Etiology. Up to within the past few years most of the literature on this subject has been devoted to the so called congenital stricture of the ureter (1).

Kelly (2) anticipates our more modern literature of the subject by stating that "strictures are caused by an inflammation in the ureteral walls produced by the commoner pyogenic cocci, by the gonococcus, and by the tubercle bacillus. The commonest form of inflammation is that due to the tubercle bacillus, and the rarest in my experience in women is due to the gonococcus."

Garceau (3), on the other hand, says, after reviewing the literature, and in the light of his own experience, "the chief cause of fibrous stricture is gonorrheal infection."

Furniss (4) takes definite issue with the prevailing opinion that most ureter strictures are congenital in origin and from a study of his cases, concluded that infection plays the important part in the production of ureteral stricture. He concludes that the infiltration in the ureter is resultant on acute hematogenous infection of the kidney, which often persists as a pyelitis, ureteritis, or secondary cystitis.

Furniss quotes Sugimura (5) as having studied the lower end of the ureters in the bodies of twenty-five patients, who had had cystitis but died of other causes. He found changes of an inflammatory type in the submucosa and muscularis and was of the opinion that the infection extended through the lymphatics and not along the mucosa.

Necker (6) exhibited before the Deutsche Gesellschaft für Urologie, at the Congress in Vienna in September, 1911, pyelograms of cases of pyelitis, all showing some dilatation of the renal pelvis, and in explanation said that they were cases of ureteral obstruction with secondary infected hydronephrosis.

Kelly and Burnam (7), speaking of traumatic stricture, voice our common experience in stating that "traumatic stricture of the vesical end of the ureter following the injuries of labor and of surgical operations, especially the Wertheim operation for cancer of the cervix uteri, is quite common. As a rule, the trauma has so interfered with the blood supply of the organ that there are lateral necrosis, a continuous leakage of urine, and ureterovaginal fistula. The spontaneous healing of such a fistula, almost invariably, means structure."

*Condensed by the author from a paper read before the section in Genitourinary Surgery, New York Academy of Medicine, January 19, 1916.

While I have seen during my hospital training cases of traumatic fistulæ of the ureter followed by stricture, I have not had such a case in my own practice and none such are included in this list. One case of slight stricture following a gunshot injury to the ureter and temporary fistula in a sixteen year old girl did not lead to symptoms and as it was an unique case, I dropped it from my report in order to list an even fifty cases, which might be classified, so far as we can judge, as strictures of inflammatory origin. In one of my cases, a stricture of the left

ureter with aseptic hydronephrosis of thirty c. c., developed four years after an outlet operation, which was followed during convalescence by an acute cystitis, for which too strong a solution of carbolic acid was given by the nurse, and this was followed within a few days by a vesicourethrovaginal fistula. I consider this stricture of the ureter as of probable traumatic origin owing to the carbolic solution, although the symptoms of hydronephrosis did not develop until after four years, when investigation revealed the stricture within the bladder wall area, and the hydronephrosis symptoms were promptly relieved after dilating the stricture.

While we must admit the possibility and probability of all the foregoing factors playing a role in the etiology of certain ureter strictures, I am firmly convinced that the majority of ureter strictures, excluding those of tuberculous and stone origin, should be classified as simple, chronic stricture, and that they have their origin in an infection carried to the ureter walls from some distant focus such as diseased tonsils, sinuses, or teeth (Hunner, 8). This conception of stricture postulates that in the majority of cases ureter infiltration is primary and that the other urinary tract lesions so often associated with stricture, such as hydronephrosis, pyelitis, and pyelonephrosis, are secondary. An analysis of my fifty cases seems to support this view.

In only two of my cases have I classified the stricture as due to gonorrheal infection. In both there was every evidence of a former gonorrheal infection such as stricture of the urethra, trigonitis, and contracted ureter orifices, the urine being clear in both cases.

In one case there was stricture of the right ureter, and the kidney colics of six months' duration disappeared after dilatation of the stricture.

The other patient, with stricture in both ureters, had a gonorrheal infection one year previously. She refused treatment after the first two examinations. and has been having kidney colics for the past eleven years since her examination.

Only three of my patients had cystitis in spite of the fact that of the twenty-seven cases with notes on culture taking, eighteen showed infection. In ten others there are notes of pus in the urine and presumably they were infected, making a probable twenty-eight cases with infected urine, but only three with cystitis. In one of these the cystitis was localized in the base of the bladder, and I considered it due to the presence of a stone in the bladder. In another there was ulcerative cystitis and stricture of both ureters with dilated infected kidney pelves, the symptoms coming on three years previously without apparent etiology, her only child being three years old when the bladder symptoms began. She had had tonsil trouble from the time she was ten until she was nineteen years of age, and I think it probable that the stricture and hydronephrosis antedated her infection and cystitis.

The third case was of ulcerative cystitis, strictures of both ureters, and colon bacillus pyelitis without dilatation of the kidney pelves. This patient dated her bladder symptoms from the birth of her last child. eleven years previously. She had not complained of kidney symptoms, although her general health was bad. All forms of bladder treatment had been without avail. After local applications for several months, the bladder ulcers were much improved, but refused to heal, and the urine showed a persistence of more pus than we should expect from the bladder condition. Investigation showed the upper tract lesions, and after dilatation of the ureter strictures, the pyelitis promptly yielded to treatment and the bladder lesions healed completely. This is the one case in my list (with the exception of the two gonorrheal cases) that I should be inclined to classify as strictures due to cystitis.

It might be argued that many of these patients had a cystitis in the past, and after absorption up the ureter lymphatics and implanting of a local ureter inflammation, the cystitis cleared up, but the histories and cystoscopy do not bear out this theory.

In only one of my cases was there an evident sequence of ureter stricture following a pyelonephritis, and in this case I am inclined to believe the foundation for the ureter strictures was laid by systemic rather than by local infection extending along the mucous membrane. This patient had an acute staphylococcus pyelonephritis following two weeks after an acute tonsillitis, and I followed the development of ureter stricture in the right ureter within four months after drainage of the right kidney, and found strictures of the left ureter a year later when the patient first began to complain of pain on this side.

While we must recognize from the writings of Schwalbe (9), Seitz (10), Englisch (11), and others, that in the developing ureter of the fetus there are well marked valves and folds along the mucous membrane, and that in the adult ureter there are certain areas of definite narrowing under normal conditions, we are forced by a careful study of the subject to get away from the former view that congenital abnormalities play an important role in any large proportion of cases of ureter stricture. In none of my cases have I seen reason to ascribe a congenital origin.

If stricture as we see it clinically were of congenital origin, we should expect the symptoms to arise in early life, although there would be exceptions. The average age of the fifty patients was 35.5 years and the average duration of symptoms was 4.5 years, making the average age at onset of symptoms thirty-one years. Of seven patients, whose history of trouble due to ureter stricture began before the age of twenty years, five had distinct tonsillitis history, one of the patients having had her tonsils removed before, and two having them removed after my treatment, and the two still retaining their tonsils having had acute attacks while under my care. Of the entire series a tonsilitis history or the presence of diseased tonsils was found in twenty-four.

In one case the double pyelitis which led to the finding of double ureter stricture occurred a few months after operation for sinus infection, the patient first coming for treatment because of rheumatism.

In one case the ureter stricture and its consequent hydronephrosis persisted and increased in spite of ureter dilatation until four abscessed teeth were discovered and removed.

Ten cases had stone in the urinary tract unassociated in time or region with the ureter stricture. Six of these stone cases belong in the group of twenty-four cases having had tonsillitis.

Nine cases had history of rheumatism, all but one of these coming under the groups with tonsillitis or sinusitis.

Three cases had a heart lesion, two of these being in the tonsil group.

These facts are at least suggestive in connection with the older theories concerning the so called "rheumatic diathesis."

The occurrence of bilateral stricture is somewhat suggestive of a systemic infection. Bilateral stricture was discovered in twelve of these cases. This condition may have been present in some others, as it has not been my custom to investigate both sides when the symptoms are confined to one side. This has been particularly true of the cases that ended in prompt recovery after treatment of the one side bearing symptoms. The bilateral character has been discovered accidentally in some cases in the course of making a functional test. In other cases one side has been successfully treated and at a later time the patient returned with symptoms in the other kidney, which were found to be due to a stricture of the corresponding ureter.

Another feature in the argument for a systemic infection is the preponderance of cases in which the stricture occurred in the broad ligament region where the ureter has its chief blood and lymphatic connections. Of the sixty-two ureters with stricture (twelve of them being bilateral) the stricture was located within the broad ligament or within six cm. of the bladder in fifty-three ureters, near the pelvic brim in eight ureters, and near the kidney in one ureter.

SYMPTOMS, ANATOMICAL RESULTS, AND DIAGNOSIS.

It is comparatively rare to have our attention directed to localized symptoms due to the stricture. The patient usually complains of a pain in the kidney region or of bladder symptoms or of both, and the stricture is found in the attempt to fathom the cause of the symptoms.

In some instances there is a local point of pain in line with the ureter, which on investigation is found to be the site of the stricture. In such cases the pain may begin in the stricture area and gradually grow more intense in the kidney region, and if we find in the urine of such a case blood, or blood and pus, we are inclined to diagnose stone in the ureter until the examination by x ray and wax tipped bougie shows the absence of stone, and the passage of the bougie reveals the presence of an obstruction. In such a case the ureter stricture may not be of sufficient density to cause an appreciable obstruction to the passage of the bougie on the first examination, and the diagnosis of stricture is suspected because of a hydronephrosis; or if hydronephrosis is not present, the first strong suspicion of stricture may occur a few hours after the catheterization by having the patient experience an unusually severe attack of pain, or if infection is present, a severe pyelitis attack. This attack follows the swelling shut of the mucosa at the stricture site due to the trauma of catheterization. By using a larger wax bulb at a later investigation, we can definitely appreciate a point of obstruction marking the stricture area.

Such cases of incipient stricture and cases of stone in the ureter which give only intermittent attacks are particularly likely to have these attacks brought on by the added congestion of the menstrual period or by the congestion following getting the feet wet, getting chilled, or "catching cold." For this reason they are often diagnosed as "ovarian attacks."

We can often palpate the area of thickening through the vaginal vault, particularly in thin women, and it is quite impossible in some cases to dif-

ferentiate between stone and stricture. Cystoscopy, particularly in cases that have a palpable thickening near the bladder, often shows an edematous reddened mons ureteris region, thus again making us quite certain we are dealing with a stone in the ureter.

It is interesting to note that a patient may have had intermittent renal colic even for years without the development of a permanent hydronephrosis. In such a case we may have great difficulty in getting by the stricture from below, and it is always surprising when we succeed in getting by a dense stricture and fail to demonstrate hydronephrosis above. When we fail to get by any obstruction by working from below, it is well to anticipate serious renal colic within a few hours because of the traumatism, and provision should be made for the patient to have hypodermic injections of morphine if necessary.

We should be on the alert for the presence of stricture of the ureter in a case of pyelitis that seems to be particularly resistant to lavage treatment. Particularly is this true if these lavage treatments are followed by acute pyelitis attacks with high temperture, chills, pain, nausea, vomiting, etc. By passing larger bulbs in such a case we can appreciate the stricture if such is present, and the pyelitis attacks after lavage will cease because of the free opening of the ureter channel at the point of stricture.

In a comparison of my infected and my noninfected cases it is seen that as a rule the noninfected cases have a history of shorter duration and renal pelves holding less than the cases with infection.

In the sixteen noninfected cases the average age was thirty-eight years, the average duration of symptoms two and a half years, and the average size of the kidney pelvis in ten of the cases was nineteen c. c., three of these holding eight, eleven, and twelve c. c. respectively, and the others holding from fifteen to thirty c. c. In one exceptional case the pelvis had reached a capacity of 360 c. c. without becoming infected. In five cases there was no note on the pelvis capacity.

In the eighteen infected cases the average age was thirty-five years, the average duration of symptoms was four years, and the average size of the kidney pelvis in fifteen cases in which a record was made was ninety-eight c. c. In four of these fifteen cases the pelvis was of normal capacity, seven to eight c. c., showing for the eleven dilated cases an average capacity of 130 c. c. In the cases with both pelves dilated, the capacity is figured on the larger pelvis only.

TREATMENT.

The ideal treatment for stricture of the ureter is by dilatation from the vesical approach. Naturally those whose work is confined to women and to the use of the Kelly speculum, have a great advantage in treating this disease. Various forms of operative cystoscopes and ureter instruments have been devised by Bransford Lewis and others which makes it quite possible to do considerable effective work from the vesical end in the male.

My work being confined to women, I shall speak only of the methods which I have used in treating stricture, these having been largely developed or suggested by Dr. Howard A. Kelly.

A glance at the figure will show the simple instruments which I use, entirely with the tubular speculum of Kelly. As a rule we use the olive tip catheter of sizes 7, 8, and 9, carrying a wax bulb eight to ten cm. back of the wax tipped end (b). Not infrequently the olive tip catheter refuses to pass when a round tip (a) or a whistle tip (c) will engage the lumen and go by the stricture. We may use the ordinary whistle tip catheter with the wax bulb or the whistle tip catheter with a gradually increasing diameter which Garceau devised for the special purpose of making functional tests (c). This Garceau catheter in sizes 11 or 13 gives a fairly good dilatation without adding the wax bulb.

At times these catheters engage the lumen better with the wire stylet left in for stiffening, and again a slight withdrawal of the stylet will result in success when the catheter has seemed permanently obstructed.

In case of failure to get by with any of these forms of flexible catheter, it is sometimes possible to make the first entrance with the metal searcher (f). By slightly curving the last cm. of the metal searcher, we can gently rotate the angled handle, thus giving the tip a variety of axes, one of which will engage and pass the stricture where the more flexible instruments will meet a pocket or shelf of mucosa and permanently obstruct. Usually after getting through the stricture area with the olive pointed metal searcher, we can withdraw the searcher and immediately get by with one of the flexible catheters which has previously obstructed; or we can follow the metal searcher with the metal bulb dilator (g), which has a slightly curved olive tip followed by a metal bulb of three mm. diameter which gives such thorough dilatation that the flexible catheter is quite certain to pass. At later treatments where a still greater dilatation is wished, the metal bulb dilator of five mm. diameter (h) may be used. It is seldom necessary to use this large metal bulb, for we can easily use the flexible catheters with a wax bulb as large as six mm. diameter. In using these very large bulbs it is well to see that the bulb is of perfect spindle shape, having no abrupt shoulder to catch on the stricture, and also to place smaller bulbs immediately in front and behind the larger bulb to give partial dilatation before the large bulb engages (b). Recently in using a large bulb with rather an abrupt shoulder on the distal side, the bulb was obstinately hung at the stricture area on its withdrawal, and it brought with it a perfect collar of mucous membrane which had been torn from the mucosa because of the abrupt shoulder. This of course creates most objectionable trauma in the site of the stricture.

In our earlier work in testing for stone in the ureter we always used beeswax (the cera flava or the cera alba of the pharmacopœia) mixed with one third or one half sweet oil, but I found that this softens the wax to such a degree that it partially crushes on meeting a narrow ureter orifice, or later on meeting the stricture; or sometimes on withdrawing the catheter a part or all of the wax is left on the proximal side of the stricture. For this reason I have given up the mixed wax and oil and use only the pure beeswax. This is soft enough to get a good

impression from stone, yet is firm enough to hang to the catheter and not crush under any ordinary conditions of obstruction.

At times, on failing to get any of the instruments to engage a stricture, I have succeeded in making the first dilatation by using the whalebone filiform searchers (e). Usually the first two or three searchers catch in the muscosa just as the other instruments have done, but after introducing three, four, or five filiforms, we can, by careful manipulation, get one of them through the stricture lumen, when by further manipulation the others will follow.

After dilatation with from two to four filiforms we can withdraw these and pass the renal catheter with the bulb, but it is generally safer to leave one or two of the filiforms as a guide and pass the metal searcher or the flexible catheter alongside the filiforms to engage the stricture lumen before the guides are withdrawn.

Before beginning work with the whalebone filiforms, we should have sterile hands or put on a sterile glove, for these have to be grasped close to the speculum at a portion of the filiform that later enters the bladder or the ureter.

RESULTS OF TREATMENT BY VESICAL APPROACH.

What can we hope for in the simpler nonoperative forms of treatment? In the cases without infection and without much renal disturbance we can look for cure. Such was the result in eight of my cases. The case numbers the duration of symptoms, and the pelvic contents before and after treatment are shown in the following table:

TABLE I.

Case No.	Duration of symptoms.	Pelvis before treatment	Pelvis after treatment.
XV	A few weeks,	30 c. c.	3 yrs. later—15 c. c.
XVII	5 years.	22 c. c.	2 yrs. later— 9 c. c.
XXI	2 months.	15 c. c.	5 mos. later—7.5 c. c.
XXII	5 years before passed ure. stone.	28 c. c.	5 mos. later— 10 c. c.
XXVII	2 years.	30 c. c.	Not seen after three treatments and complete relief of symptoms.
XXVIII	9 years.	15 c. c.	3 yrs. later—Reports no further renal attack—Is pregnant for the third time since treatment.
XXXV	18 months.	22 c. c.	4 mos. later—10 c. c.
XL	3 months.	40 c. c.	Not seen after two treatments.

In certain other cases, even with infection, if the kidney pelvis is not too dilated, we get brilliant results in permanently clearing up the symptoms and the infection through dilatation and lavage. This occurred in five of my cases, two with bilateral stricture and pyelitis.

TABLE II.

Case No.	Duration of symptoms.	Pelvis before treatment.	Pelvis after treatment.
XXIV	11 years.	Bilateral, colon, no dilatation.	Free of pus and bacteria.
XLI	One year or less.	30 c. c. staphylococcus.	Free of pus and cocci. Pelvis contents 8 c.c. six months later.
XLIII	4 months.	Bilateral, colon, no dilatation.	Free of pus and bacteria.
XLVII	Pyelitis one week.	15 c. c.—colon.	Free of pus and bacteria.
XLIX	10 months.	40 c. c.—colon.	Free of pus and bacteria. Pelvis contents 30 c. c. two months later.

In other cases with infection and large pelves we may be unable by lavage to rid the patient of infection probably because of the permanently sacculated pelves, but we may place them in apparent perfect health by doing away with the ureter obstruction, thereby relieving their pain and their toxic symptoms. Case XVI was admitted to the Johns Hopkins Hospital in July, 1912, with repeated chills and a hectic fever ranging as high as 104° F. The right kidney had a capacity of 100 c. c. and yielded a turbid purulent urine. The left kidney held 120 c. c. and was secreting a thick, turbid urine as of a pyonephrosis. Both ureters had two or three infiltrated areas near the bladder, and cultures revealed colon bacillus from either side. After dilating the strictures and washing the kidneys with silver nitrate solution, the patient promptly improved and left the hospital, feeling well and with urine from each kidney showing only microscopic pus and bacteria. This patient has remained in good health, and for the past two years I have seen her only two or three times a year. On November 15, 1915, the patient came at my request and had dilatation of both ureters. The urine was macroscopically clear, but contained microscopic pus and bacteria. The right pelvis took forty c. c. to the point of discomfort and the left took fifty c. c., each side returning forty-five c. c. in a steady stream.

In three of my cases with infection, the patients' symptoms were relieved by treatment, but I have been unable to follow them to learn of the final kidney condition by cystoscopy.

Case XIV with attacks of pain in the kidney for two years, enlarged, inflamed tonsils, and arthritis, had a stricture about three cm. from the bladder, and a kidney pelvis of twelve c. c. capacity, with a staphylococcus infection. After a few dispensary treatments we lost track of her.

Case XXIV had a stone in the bladder with symptoms referable only to this. The x ray picture revealed another small shadow in the left ureter region. On investigation this shadow was found to be outside the ureter, but the ureter had a stricture in the bladder portion and another about four cm. from the bladder. The kidney pelvis held twenty-one c. c. and was infected with colon bacillus. After a few treatments the strictures were well dilated and the pelvis reduced to fourteen c. c. The patient went to her home in North Carolina before the infection was cleared, and a recent letter, almost four years after her treatment, states that she is perfectly well.

Case XLV I saw in August, 1915, when the woman was three months pregnant. She had had the symptoms of a pyelitis for four days. Palpation in the left ureterovesical region revealed a small mass, taken to be a calculus. The left mons ureteris was swollen and red and measured one cm. in diameter, being elevated above the surrounding mucosa 0.5 cm. The metal searcher discovered a grating as of stone or stricture just within the ureter orifice. The metal telephone catheter failed to sound stone. The stricture was dilated first with the three mm. and then with the five mm. metal bulb dilator, the latter splitting the mucosa somewhat and causing bleeding. The kidney pelvis held eighteen c. c. and the urine from the kidney was smoky and turbid, containing pus, blood, and bacteria. Unfortunately a culture was not taken. This patient was

a physician's wife, and as her symptoms cleared within two or three days, I have not seen her since. Her labor is due about the last of February and her husband reports that the urine is perfectly normal.

In another group of three cases, each with bilateral infected pyelitis, the end results have been unsatisfactory because of a failure of the patients to persist with treatments after securing enough dilatation to free them from the severe attacks of pyelitis.

TREATMENT BY OPERATION.

If all the methods of vesical approach fail, we must consider operative relief. No form of operation will be undertaken until as complete investigation as possible has been made of both sides. Stricture of the ureter is so often bilateral that we cannot afford to take anything for granted in dealing with these cases.

If investigation shows stricture of but one ureter, and this side associated with a kidney of little or no functional value, conservatism usually calls for extirpation of the injured or dead kidney. This was done in six of my cases with entirely satisfactory results.

If the stricture is high at the junction of the kidney pelvis with the ureter, we may follow Fenger in doing some form of pyeloureteroplasty. Actual stricture at this point is extremely rare and the valvelike obstruction formed by floating kidney can usually be overcome by mere high fixation of the kidney, as I have done in a number of cases with excellent results.

If careful examination at the time of operation leads us to suspect an organic narrowing at the pyeloureteric junction, a pyelotomy and careful dilatation may be done in addition to the kidney fixation, or if the pelvis is very large, a partial pyelectomy may be done, being careful to dilate if the orifice into the ureter is at all narrowed.

If the stricture is lower and about the lumbar or pelvic brim region, it has been recommended to sever above the stricture and implant into the colon or in the loin region.

If the stricture is low and near the bladder, as a vast majority of these strictures are, it has been the custom to implant the severed healthy end into the colon or bladder. I have never made a colon transplantation, as I have but little faith in our ability to make the transplant in a manner to prevent future infection of the kidney.

I am familiar with Coffey's brilliant results on the dog, and with the apparent satisfactory results of his and Mayo's colon transplants in the human subject, but I fear time will not bear out the perfection of these results.

I have done bladder implantation in two of these fifty stricture cases with indifferent or questionable results in both. I say questionable results, because in neither case could I later enter the ureter with a catheter from below. Both patients have been in good health since the implantation, but I suspect there may have formed strictures at the site of the implantation with gradual destruction of the kidney.

I wish to emphasize a method for handling these cases by operation, which I have not seen mentioned in the literature, but which I am sure must have been done by many surgeons and which has probably been described before, viz., the treatment by retrograde dilatation. Certainly every surgeon must follow his ureter stone extractions by dilatation of the usual area of infiltration about the stone.

The ureter is exposed by an extraperitoneal incision, incision is made into its dilated portion above the site of stricture, and increasing sizes of the French gum elastic bougies (see fig. d), or metal sounds are passed until the stricture is dilated to a diameter of from 0.5 to one cm. The ureter incision is then closed with catgut, reinforced, if thought necessary, with silk or linen. A wick drain is usually left in the extraperitoneal incision for forty-eight hours to take care of possible contamination by the escaped urine at the time of operation or of postoperative leakage and the excessive serum secretion following the extraperitoneal operation.

If the dilatation has not been entirely satisfactory, or if there has been much trauma to the ureter, I leave it open, or close it carelessly with catgut to favor urine drainage in case temporary swelling shuts off the traumatized stricture area. In such cases two or three small wicks are dropped to the area of ureter incision and left some days or until there is certainly no urine leakage.

A McBurney incision is suitable in most of these cases, but a semilunar line incision is more useful, for it can be enlarged up or down to suit the exigencies of the case, and through a moderately long semilunar line incision we can easily palpate from kidney pelvis to bladder.

With care we can preserve the intercostal vessels and nerves crossing this incision to the rectus muscle, simply by deflecting and working between them.

I have treated eight cases by this retrograde dilatation, five in which it was impossible to dilate from below, two in which stricture of the ureter was found when stone was being looked for, and one in which ureter stricture had been successfully treated from the vesical approach one year previously, but in which the stricture again swelled shut sufficiently to cause kidney symptoms in the course of an attack of acute gonorrheal salpingitis.

The results in these eight cases treated by retrograde dilatation have been perfect in six, so far as measured by relief of symptoms and ability easily to catheterize later from below. In one case, my first one, in which I was looking for stone and failed to find it, but found the ureter dilated to one cm. diameter from the bladder to the dilated kidney pelvis, I found a dense stricture in the bladder area and dilated it with the uterine sound only, which probably made a diameter of only three mm. I heard, one or two years later, that this patient had acquired symptoms again and had a stone removed from the kidney. I have questioned the accuracy of this report, especially as the patient had the kidney removed at a third operation. It is possible that I overlooked a floating stone temporarily lodged in a kidney calyx, but I think it more likely that the symptoms returned and persisted because the stricture was not sufficiently opened. My x ray had shown a questionable shadow in the kidney region.

The cases least suited for retrograde dilatation are those in which previous testing of the capacity of the kidney pelvis and ureter and pyelography have shown an absence of enlargement of the lumen above the site of stricture. In these cases the ureter is found too small above the stricture to admit large dilators, and if it is at all possible to get by from the vesical approach, we should be satisfied to do as well as possible by this route, although it may require a long and tedious course of treatment.

CONGENITAL SYPHILIS.

Report of a Remarkable Case,

By J. P. Jones, M. D.,
Nez Percé, Idaho.

Syphilis has been known to the profession as a morbid entity since the time of the siege of Naples by Charles VIII (1494-1495), but it has been only during the past few years that remarkable strides have been made in its diagnosis and treatment, both of which have become comparatively easy in the primary and secondary stages, and in most cases of the tertiary. But the long neglected undiagnosed and untreated congenital syphilitics who present hideous deformities of almost every tissue and organ of the body, are subjects whom many of us are not anxious to treat, and whom we had much rather see go to some one else. But they offer a field for patient work that is usually rewarded with splendid results. Badly damaged organs cannot be made normal, but such organs often can be made to function in a manner consistent with comfort and health, greatly to the patient's relief and the physician's satisfaction.

I report the following case not because there is anything especially unusual about it except its severe nature, but chiefly to impress the fact that patient treatment can do untold good to many of these most miserable of all people.

Case. Lillian W., aged eighteen years, was admitted to Doctor Ashhurst's orthopedic service in the Episcopal Hospital, Philadelphia, August 19, 1913.

Family history: Father died sixteen years ago of heart disease, which was most probably syphilitic, for as Stoll says sudden cardiac death occurring in middle life is almost always syphilitic. (H. F. Stoll, Role of Syphilis in Hypertensive Cardiovascular Disease, *Albany Med. Jour.*, August, 1915). Mother died four years ago of cancer of the stomach (?). The first child lived for two years. This patient was the second child. Five other children followed, but none of them lived more than two days.

Personal history: There was nothing of moment in the patient's personal history, until the age of seven years. Prior to this her health had been good, except for some of the acute exanthemata common to childhood. She was probably a little large for her age. At the age of seven years she accidentally ran a piece of glass into her nose just below the left eye; the glass was removed by a physician. About nine months after this accident her mother noticed that the child's nose was beginning to sink in slightly at the bridge. About three months later, the entire septum had disappeared, thus permitting her nose to lie flat.

At the age of ten years she was four feet nine inches in height. She began menstruating at the age of thirteen years, and this function was regular, occurring every twenty-eight days and lasting two days. During her thirteenth year she became bedridden, owing to the following occurrences: Her right leg in one night became flexed at the knee, and remained in this condition. However, previous to this time, she had had pain in the knee joint, and at times there was a grating in the joint on flexion and extension. About nine months later, she fell and sustained a greenstick fracture of the right leg. Three years later (two years before admission), the left knee became flexed in a manner similar to the right; this occurred during one night also. She stated she had not previously had any pain in the left knee, as she had had in the right. About the same time the right forearm became slightly flexed at the elbow, and she was unable to extend it completely. One year ago, the patient attempted to straighten out the left lower extremity and as a result fractured the femur about its middle. This fracture united with an anterolateral convex deformity (Fig. 1), and one week before admission she refractured it, coming into the hospital with no union. About one year ago the middle of the right forearm became markedly bent, with the convexity

Fig. 1.—Pathological fracture of left femur; note deformity of legs and foot.

on the flexor surface (Fig. 2), the bones forming an angle of about 120°.

For the past five years this girl had not once been removed from a wheel chair. In this she spent her days and slept at night, used the bedpan when necessary, and had the pillows and coverings changed as occasion demanded, but with great difficulty and suffering. She lived with her aunt, all the members of her immediate family having perished from the disease which was the only legacy she had received from them. She spent her life in a little room back of a grocery shop kept by her aunt, and seldom or never saw any outsiders.

On admission the patient was seen to be anemic, had a very pasty appearance, and was exceedingly hypersensitive, emitting the most frightful screams at the slightest attempt to turn her in bed or bathe her. She was entirely unable to move either of her lower extremities, and she had only limited motion in her upper extremities. She had to be fed, and was in every way absolutely helpless. She was an excessively miserable looking creature. She was at this time so repulsive to look at, that one of the resident physicians who went to look at her, as a pathological curiosity, became nauseated at the sight, and that one of the nurses in training actually vomited after getting one good look at her!

Her hair was light in color, and there was no evidence of alopecia. The eyebrows were thin, and there was an entire absence of pubic and axillary hair. The pupils were equal and reacted normally to light and accommodation. Over the left lacrymal duct there was a swelling that apparently contained pus. The bridge of the nose was absent, and the upper part of the alae and the tip of the nose

Fig. 2.—Showing deformity of arms and right leg.

had ulcerated away (Fig. 3). A great part of the septum was missing, and the under part of the nasal bone was eroded, together with the soft parts underlying them. There was a continuous mucopurulent discharge from the nose. (Examination of this by Dr. C. Y. White showed no evidence of Treponema pallidum).

The tongue was normal. The teeth were not typically Hutchinson in type; they were normal in size, but the two upper incisors were very loose and movable. The roof of the mouth was normal. The chest was flattened laterally, projecting in front (pigeon breast). Expansion was fair, but the tactile and vocal fremitus were increased over the right chest posteriorly. The heart was apparently normal. The abdomen was slightly protruding, and the liver extended to within about one inch of the umbilicus. The spleen was slightly enlarged.

The muscles about the right shoulder joint were more or less atrophied, but the joint was freely movable. The right forearm was held in acute flexion with elastic resistance to extension. The bones of the forearm were very elastic and weak, scarcely being able to support the weight of the hand. There was marked anterior angularity of the mid forearm, the forearm was very tender, the patient screaming at the least manipulation. The proximal phalanx of each finger presented a marked spindle shaped hypertrophy (typical syphilitic dactylitis; Fig. 4).

The left upper extremity was practically the same as the right, except that there was not so great angularity in the forearm; the deformity suggested an old Colles's fracture. The left lower extremity presented a fracture of the femur about the middle third; the fragments could easily be felt, and their movements seen beneath the skin on the anterior surface of the thigh. The leg, with the lower femoral fragment, was in marked internal rotation on the upper fragment. There was no union. The left knee was in a position of fixed flexion of about 90°. The left leg was very flexible at its lower third, with very little of the tibia present. The dorsal surface of the foot was swollen, and the foot was in a position of marked valgus. The toenails were loose, and pus poured from beneath them.

The right lower extremity presented a flexion at the knee of about 90°. The knee was not ankylosed, but very little movement was possible. The lower third of the leg was very flexible indeed, and the tibia could not be felt at all at this level, and skiagraphs showed its continuity to be lost (Fig. 5). When the calf of the leg was lifted from the bed, the lower third of the leg dropped to a position at right angles with the upper portion. The foot was large and pudgy, and was in considerable equinovarus deformity. The patient sat or reclined in bed (she could not lie down) with the right leg drawn under her and the left knee supported on the right one.

Immediately after her admission a Wassermann reaction was made on the blood serum, and was found to be plus four. She was put on protiodide of mercury and potassium iodide, but these had to be discontinued in about two weeks, owing to soreness of her gums. Scrupulous cleanliness was observed, and she was given a special diet of the most appetizing food. She was regularly given general massage, and was kept on the porch day and night in all weathers.

On August 13, 1913, the patient was given 0.4 gram of neosalvarsan, which caused nausea for four or five hours. Her thighs were gradually separated by interposition of pillows. On September 20, 1913, she received another injection of 0.4 gram of neosalvarsan; this was followed by no reaction. The abscess of the lacrymal duct was incised and dressed.

Injections of neosalvarsan were continued about every two weeks, and by October 10th the patient seemed to be improved in many ways. Her color was much better. Her teeth were not so loose. Both forearms had a much wider range of motion. The bones of the forearms and legs seemed to be thickening; they were certainly much stronger, and she could be moved about in bed without exciting such great pain. The sinus in the lacrymal duct did not improve very much under repeated dressings, and the purulent exudate from beneath the toe nails did not improve. By October 20, 1914, the discharge about the toes had ceased and the patient could lift

Fig. 3.—Erosion of alæ and tip of nose.

FIG. 4.—Typical syphilitic dactylitis.

up her entire right lower extremity without pain.

By November 13, 1913, the ulceration of the left eye had almost healed. An adhesive plaster extension apparatus was attached to the left knee, and weights were hung to it over the side of the bed, in an effort to produce abduction of the left thigh. The girl was now able to feed herself. On November 17, 1913, we saw that the extension on the left knee had produced marked lessening in the adduction. The patient was now given one grain of salicylate of mercury in oil, intramuscularly every two weeks. She could flex and extend the right leg on the thigh, but could not extend it beyond a right angle. She was evidently gaining in weight. Her appetite was fair, and she did not complain of pain while she was being bathed and moved about in bed. She continued to give a plus four serum Wassermann.

November 20, 1913, the right lower extremity is put on a right angle splint, like a double inclined plane, and this is held perpendicular to the bed; but attempts to extend the leg on the thigh beyond a right angle produced a marked bend of the leg a few inches below the knee instead of extending the knee joint (Fig. 2). November 23, 1913, the splint to the right lower extremity holds the leg in very good position, correcting the bend below the knee. The left thigh has now been abducted until it lies in the long axis of the body. November 30, 1913, there is some soreness of the gums and some abdominal pain, so the mercury injections have to be discontinued for the time being.

January 1, 1914, the mercury salicylate has been given again for some time without ill effects. The patient's general appearance has been greatly improved. The ulcerating area at the inner angle of the left eye has healed. The right knee can now be extended to 105° (15° more than a right angle). January 20, 1914, the patient was placed in a chair with her feet in another chair today. She sat up for several hours in perfect comfort.

March 17, 1914, the luetin test was done two days ago by Dr. J. V. Klauder. Today it shows an area of erythema about two cm. in diameter, a markedly inflamed papule at its centre, with slight induration surrounding it. She is now given one grain of mercury salicylate intramuscularly every two or three weeks. At times the intervals have to be lengthened owing to soreness of the gums. The Wassermann blood serum reaction continues to be plus four. June 5, 1914, the patient sits in a chair all day now and seems to be feeling perfectly well. Braces were applied to her forearms today in the hope that they might be somewhat straightened. July 8, 1914, the general condition is greatly improved. The patient is discharged and referred to the orthopedic dispensary for further treatment. She is instructed to continue her mixed treatment as in the hospital, returning at suitable intervals for the mercury injections.

FIG. 5.—Right leg; extreme bone atrophy, occurring in hereditary syphilis; the continuity of the tibia is lost, that of the fibula preserved.

January 7, 1915, the patient is readmitted to the hospital. The sinus below the inner canthus of her left eye has opened again. She is now able to get in and out of her wheel chair and into and out of bed alone, but she cannot stand, even with support. She has no pain in any of her joints. While at home she tried to stand and fell, breaking her right leg above the ankle; she kept it on a splint for three weeks, when it had apparently united firmly. (This is the leg in which the tibia had become so atrophied that at one portion it did not cast any shadow in the x ray Fig 5, made August 20, 1913). She can use her hands almost as well as a normal person; she

Fig. 6.—Atrophy and deformity of right radius and ulna.

sews, embroiders, and writes a legible hand. She can extend her right elbow to 125° and flex it to 35°. The right forearm at the middle shows an anterior angularity of 130°. Wrist motion is nearly normal. The left elbow can be extended to 135° and flexed to 35°. There is subluxation forward of the left wrist, with some thickening of the lower end of the radius and deviation of the hand to the ulnar side. Rotation in each forearm is about half normal. The fingers are nearly normal.

The patient can extend her right knee to 135° and flex it to 35°. The bones of the right leg are bent backward in the upper third to an angle of 140°, with the apex on the calf surface. The tibia and fibula are tender above the ankle (site of the recent fracture). The right foot is in a position of equinovarus. The ankle can be flexed to 120° and extended to 130°. The foot is large and pudgy. The toes are nearly normal. The left knee can be extended to 120° and flexed to 85°. The left leg is straight. The foot is in considerable valgus deformity. The flexion in the ankle joint is 90° and extension to 105°. The liver and spleen seem smaller than when she first came under treatment sixteen months ago.

On readmission to the hospital she continued her old treatment of one grain of mercury salicylate intramuscularly every two weeks, with potassium iodide in increasing doses until iodism, then discontinuing for two or three weeks. January 30, 1915, the Wassermann serum reaction was plus 2; on March 10, 1915, plus 2.

On April 28, 1915, Doctor Ashhurst performed manual osteoclasis of the right radius and ulna, under gas-oxygen anesthesia. Union was fair and position good by the middle of June, when she was discharged for another vacation.

On October 20, 1915, the patient was readmitted to the hospital, for the purpose of osteoclasis of the left forearm, which was done by Doctor Ashhurst. Union and position were good.

January 23, 1916, the patient, who has been home since the last operation, writes, asking to be readmitted, and inquiring about operations on her lower extremities, and for the formation of a nose.

While we have not obtained either an anatomical or laboratory cure in this case, still our results have been gratifying and have well repaid us for our efforts. In less than two years this breathing piece of pathology has been changed, by rather simple treatment, from a miserable, loathsome, deformed, ulcerating, hypersensitive screaming wretch to a much less deformed, happy, fairly healthy person, who can use her mind and her hands in various methods of interesting and profitable work. The most interesting part of the surgical work required could not be done until this stage was reached. It now remains to overcome the deformities of the lower limbs by a series of more or less complicated operations, to teach her to walk, and to form a new nose. Her own changed attitude to life is evidenced by the fact that when she came under treatment first, she said the absence of her nose was "the least of her troubles." Now she regards it as almost the greatest.

INTRADURAL NERVE ANASTOMOSIS IN SELECTED CASES OF POLIOMYELITIC PARALYSIS.

A Preliminary Report.

By Norman Sharpe, M. D.,
New York,
Neurological Surgeon, Post-Graduate Medical School and Hospital.

Acute anterior poliomyelitis, a disease of childhood, attacks the motor cells in the anterior horns of the cord, more frequently those supplying the leg. Many of the cells so attacked later return to normal, while others are destroyed, with consequent atrophy of their nerve roots and permanent paralysis of the muscles they control. The object of this operation is to secure restoration of function to the paralyzed muscles by intradural anastomosis of a nerve root whose motor cells are active, to a paralyzed nerve root. Naturally the live roots selected must be those whose normal function can be dispensed with, such as the twelfth dorsal, or first and

second lumbar roots which supply muscles of the trunk having other nerve supply.

This operation is somewhat similar to nerve suturing in brachial plexus palsy resulting from injury during birth, where operation often results in a useful arm; it possesses this advantage, however, that in intradural root anastomosis there is not the preëxisting scar tissue that is found in brachial plexus palsy, which tends to hinder nerve regeneration, with later formation of adhesions and scar tissue. There are many cases in which the paralysis in one or both legs following acute anterior poliomyelitis is so complete that little, if any improvement can be obtained by orthopedic methods. When the extremity is almost, or completely paralyzed, tendon transplantation cannot be used, and only braces are of value. Though they enable the child to stand and in some cases to get about with the aid of crutches, braces do not correct the lack of growth in the limb due to the nerve paralysis, and as the child grows older the difficulty in walking is increased. Naturally, the ideal procedure in these cases would have for its object the restoration of nerve continuity with consequent normal function of the paralyzed muscles. This has frequently been attempted in cases of anterior poliomyelitis by anastomosis of the peripheral nerves in the affected extremity, though with but little, if any success. The chief cause of failure is that the "live" peripheral nerves available for anastomosis are only near normal, for they carry many diseased fibres, owing to the complex anastomosis of the roots in the lumbarsacral plexus.

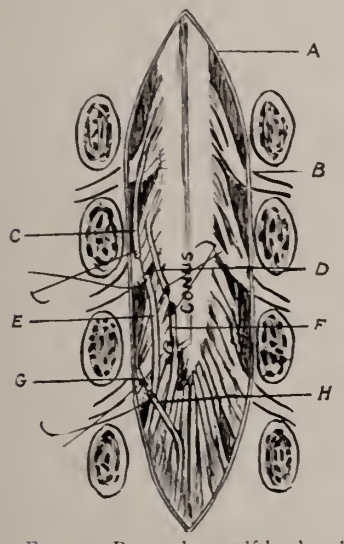

FIG.—a, Dura; b, twelfth dorsal nerve; c, anterior root of twelfth dorsal; d, anterior root of first lumbar; e, anterior root of fourth lumbar; f, anterior root of second sacral; g, anterior root of second lumbar; h, anterior root of fourth sacral.

In 1907, Basil Kilvington conducted upon animals a series of experiments in nerve anastomosis in the spinal canal. He joined the central end of the seventh lumbar nerve in the dog to the distal portions of the second and third sacral nerves, which control the bladder, and several months later stimulation of the seventh lumbar nerve caused expulsion of the bladder contents, demonstrating the efficiency of nerve anastomosis and the renewal of nerve function. The nerve suturing was done in the spinal canal, but extradurally. Kilvington's experiments had for their object the relief of bladder paralysis in traumatic cases.

In 1912, Frazier and Mills reported suturing the first lumbar root to the third sacral of one side intradurally in a case of traumatic bladder paralysis, with fair results. Had the nerve crossing been done upon the other side also, the result would doubtless have been better.

For the past two years the writer has carried out a series of experiments upon animals in nerve anastomosis in the spinal canal, with the object of caudal root anastomosis in marked cases of paralysis of a lower extremity, following poliomyelitis. The results of these experiments will be given when a later report of the following three cases is made. Of course, no results of nerve regeneration are to be expected until a period of at least six months has elapsed since operation.

These three cases, which were operated in, in conjunction with Dr. William Sharpe, are reported at this early date for two reasons: 1. The results of previous experiments, and of the writer's own experiments on animals are such as to promise well for restoration, at least partial, of function; 2, as the individual surgeon sees but a few patients with the extensive paralysis of the legs suitable for this operation, this report may arouse the interest of other neurological surgeons in these otherwise hopeless cases. The operation of intradural nerve anastomosis of the cauda equina roots is not more formidable than the frequently performed operation of laminectomy with opening of the dura. Beyond rigid asepsis and a carefully worked out technic the greatest requirement is patience and knowledge of the anatomy of the cauda equina and the arrangement of the nerve roots.

CASE I. F. S., male child, aged five years, normal and healthy until eighteen months old, when he had poliomyelitis, causing paralysis of both legs. Was taken to Rockefeller Institute and at the end of six weeks could use the left leg normally, but there was no improvement in the right leg, and complete paralysis of that leg has persisted to the present time.

Status: Complete paralysis of right leg below groin. Reflexes absent. Atrophy of thigh and calf, more marked in calf. No contractures. Sensation normal. Reflexes, motion, and strength normal in left leg. Child was well nourished and well developed, except for atrophy of right leg. Electrical reactions: a. c. c. greater than c. c. c.

Operation: First stage, February 16, 1916, laminectomy—a four inch median incision was made and the spinous processes and laminæ of twelfth dorsal and first, second, and third lumbar vertebræ were removed, exposing the dura. Wound closed with catgut and silk.

Second stage, March 3, 1916, wound reopened and dura and arachnoid incised. The right twelfth dorsal anterior root was isolated, cut near its passage through dura, and united by a single fine silk suture to the fourth lumbar right anterior root, which was severed near the conus. In a similar manner the first and second lumbar right anterior roots were united to the first and second sacral anterior roots, respectively. Dura was closed with silk, muscles with catgut, and skin with silk. No drain.

Convalescence uneventful, and child left hospital, March 31st, in good condition.

CASE II. J. V. H., male, aged sixteen years; child was healthy until fourteen months old, when he was attacked by poliomyelitis, and was ill two weeks. After a few weeks, he was normal again, except for a complete, flaccid paralysis of left leg. After a year's lapse, he could feebly and slightly flex knee and ankle and move toes slightly. No further improvement occurred.

Status: Well nourished and well developed boy. Flaccid paralysis of left leg with absent knee and ankle jerks. Sensation unimpaired. Though there was feeble motion at knee and ankle, leg was practically completely paralyzed as far as use was concerned. Electrical reactions in paralyzed muscles: a. c. c. greater than c. c. c.

Operation, first stage, March 10, 1916, laminectomy—median incision and removal of spinous processes and

laminæ of the twelfth dorsal, first and second lumbar vertebræ, a matter of some difficulty in this case, because of the thick and highly arched laminæ. Because of free bleeding from retrodural vessels, it was necessary to divide the operation into two stages. Wound closed with catgut and silk. Second stage, suture of roots, March 20, 1916; wound reopened and dura incised. The left twelfth dorsal anterior root, which was accompanied by a large vein was isolated, severed, as in Case 1, and united to the left fourth lumbar anterior root. The left first lumbar anterior root was likewise sutured to the left second sacral anterior root. Wound closed in usual manner.

Convalescence uninterrupted, and boy left hospital April 6, 1916, in good condition.

Case III. G. R., female, aged six years; normal child, until two years old, when she had an attack of vomiting with fever and next day both legs were paralyzed completely, and the trunk muscles also involved, but to a less extent. In the following months the paralysis of the trunk disappeared entirely, the right leg slightly recovered, but the left leg remained completely paralyzed.

Status: Well nourished and developed child. Marked flaccid paralysis of right leg, being able to move knee and ankle feebly and to extend toes weakly. Complete flaccid paralysis of left leg. Reflexes absent in both legs. Sensation normal. Had had the usual treatment by massage and electricity. Had worn braces for some time, and with a crutch was able to get about a little, but with difficulty. Electrical reactions: a. c. c. greater than c. c. c.

Operation, first stage, March 13, 1916, laminectomy—median incision and removal of spinous processes and laminæ of twelfth dorsal, first and second lumbar vertebræ and dura widely exposed. Closure of wound by catgut and silk.

Second stage, March 24, 1916, suture of roots. Wound reopened and dura incised. The twelfth dorsal anterior root of left side was isolated, severed, and sutured to left fourth lumbar anterior root, and likewise the first and second lumbar anterior roots of left side were united to the first and second sacral left anterior roots, respectively. Dura closed with silk, some extradural bleeding requiring packing, which was removed when skin sutures were inserted. Convalescence was uneventful and child left hospital April 11, 1916, in good general condition.

Though those three cases were operated in in two stages, the writer believes that the one stage operation is perfectly feasible and that improvement in technic and team work will make it possible to complete the operation at one session.

315 West Ninety-seventh Street.

THE CONTENTS OF OVARIAN CYSTS.*

A Preliminary Report upon Their Toxicity,

By J. T. Leary, M. S.,
Philadelphia,
H. J. Hartz, M. D.,
Philadelphia,
and Philip B. Hawk, Ph. D.,
Philadelphia.

From the Laboratory of Physiological Chemistry and the Laboratory of Gynecological Pathology, Jefferson Medical College and Hospital.

Several investigators have made interesting chemical studies of the contents of ovarian cysts, chiefly of the multiple cyst adenoma, or the proliferating variety. These cysts have a content of variable composition. They contain a mucous secretion, clear and transparent, or turbid from cell debris and blood. A large amount of blood admixture may give the fluid a chocolate color. The flocculent particles frequently seen in the cyst contents are made up of cell debris, cholesterol, blood corpuscles, and fat droplets. The pseudomucinous are by far the most common of the large ovarian cysts; several are on record weighing over 200 pounds. The contents of these proliferating cysts have a variable composition, but are generally characterized by the slimy or ropy consistence, the grayish yellow, or chocolate color, and the relatively high specific gravity, 1.015 to 1.025.

Scherer (1) discovered protein substances in ovarian cysts and named them metalbumin and paralbumin. He considered the former an albuminous body; but later investigations by Hammarsten (2) proved these substances to be pseudomucin. Hammarsten considers colloid and pseudomucin (metalbumin and paralbumin) to be characteristic constituents of these cysts. Pfannenstiel (3) designates the colloid as *B*-pseudomucin. This colloid is a gelatinous substance, insoluble in water and acetic acid and soluble in alkalies. It is not precipitated by acetic acid and potassium ferrocyanide. Colloid is very closely related to mucin and is considered by some as a modified mucin.

Pseudomucin gives the typical ropy appearance to contents of ovarian cysts. Hammarsten gives the following composition for pseudomucin: Carbon 49.75, hydrogen 6.98, nitrogen 10.28, sulphur 1.25, oxygen 31.74 per cent. This body like mucin gives a reducing substance (glucosamine) when boiled with acids. With water pseudomucin gives a slimy, ropy solution; it does not coagulate on boiling, but only becomes milky or opalescent. Unlike mucin, pseudomucin solutions are not precipitated by acetic acid.

Mitjukoff (4) isolated from the colloid contents of an ovarian cyst a substance called paramucin which differs from pseudomucin in that it reduces Fehling's solution before boiling with acid.

Other chemical studies on contents of ovarian cysts have been made by Fr. Müller (5) and Neuberg and Heymann (6), who have shown that glucosamine is the only carbohydrate regularly found in these structures. The presence of chondroitin sulphuric acid has also been reported.

Otori (7) has made extensive studies on the hydrolytic cleavage products of pseudomucins obtained from ovarian cysts. Beside the carbohydrate derivative of levulinic acid and humous substances, he names the following: Leucin, tyrosin, glycocoll, aspartic acid, glutamic acid, valerianic acid, arginin, lysin, and guanidin. Pregl (8) failed to find glycocoll, but reports alanin, prolin, phenylalanin, and tryptophan among the hydrolysis products.

Other protein bodies found in cystic fluids are mentioned by Hammarsten as seroglobulin and seralbumin, and peptone, mucin, and mucin peptone. Fibrin occurs only in exceptional cases. The quantity of mineral bodies on an average amounts to about one per cent. The amount of extractive bodies (cholesterol and urea) and fat is ordinarily 0.2-0.4 per cent. The remaining solids, which constitute the chief mass, are protein bodies and pseudomucin.

Auché and Chavannas (9) have contributed further notes on the experimental study of intraperi-

* Read before the Philadelphia Pathological Society, March 23, 1916.

toneal injections of contents of ovarian cysts and their effects on the organs of the rabbit so injected. They made exhaustive study of this phase of the subject.

The object of this work was to ascertain whether any of the several varieties of ovarian cysts contained toxic substances, and if so the isolation and identification of these substances. Accompanying this study an analysis of the chemical constituents of the cysts was also made whenever the contained fluid seemed of sufficient interest. Bacteriological studies were made upon the contents of each cyst. Several varieties of cysts were studied, namely: Three multiple proliferating cyst adenomata, one papillary proliferating cyst, one multiple follicular cyst, one simple cyst of ovary.[1]

The study of the toxicity of the cyst contents was made by the intraperitoneal injection of ten c. c. of the contents into guineapigs, the effect upon the experimental animals being judged by the subsequent weight and temperature. Glycerol bouillon, gelatin and glucose, glycerol agar, were used in the bacteriological studies. The chemical examination consisted, as a rule, in the identification of the protein contents of the cystic fluid.

Cyst I (laboratory No. 7799) was removed from a patient, M. B., fifty years of age; nativity, American, white. Widow, telephone operator. She gave the following history: Did not recall having been sick until the present illness. Married at sixteen years of age, had four normal labors and two abortions. For eight years had prolapsus of uterus, necessitating the use of a pessary. Operation performed in Jefferson Hospital by Dr. P. B. Bland for cystocele and rectocele. Abdomen was opened in midline and a large ovarian cyst of left side and smaller ovarian cyst of right side were removed. Patient made good recovery. The laboratory report was as follows: Specimen consisted of two parts, the larger weighed 3 kilos and measured 23 by 15 by 14 cm., was an unilocular cyst with thin translucent walls with a gray and glistening surface. The tube was elongated and showed no other gross change. The second part of specimen was an ovarian cyst, 5 cm. in diameter, portion of ovary forming cyst wall. The tube showed no gross change. One section of second cyst wall was fixed in formalin. The microscope showed the section to be a thick and dense fibrous tissue cyst wall without epithelial covering. The diagnosis of the specimen that was also studied chemically was multiple cyst adenoma of ovary. The chemical examination of the smaller cyst showed contents about 50 c. c. of a clear serous fluid. Two animals were injected and plates poured.

	I	II		I	II		I	II
Agar colonies,	—	—	Gel.,	—	—	Boullion,	—	—
	0	0		0	0		0	0

Both animals were down to original weight on following day and showed no rise in temperature.

Cyst II (laboratory No. 7724). Removed from a patient, K. K., forty years of age, white, married, nativity Greek, housewife. The patient was admitted to the hospital with the following history: For past year noticed an enlarging mass in lower abdomen, which she thought might be due to pregnancy, but during this entire time she had irregular uterine bleeding. Examination revealed a large mass in lower abdomen, extending above umbilicus, more marked on left side. Operation in Jefferson Hospital, February 14, 1914, by Dr. J. M. Fisher. The abdomen was opened and a large ovarian cyst was removed by ligating and cutting through narrow pedicle. Patient made a good recovery. The following report was rendered by the laboratory: Specimen weighed 2.5 kilos, measured 23 by 18 by 12 cm. Surface was pearly gray, capsule was thin, contents thick fluid. The mass was irregularly globular, had several smaller lobulations separated by shallow grooves. The tube was spread out over cyst and measured 15 cm. in length. Three sections were fixed in formalin. The microscope revealed multiple cysts with thin septa separating them. Some of the spaces were bordered by cuboidal epithelial cells, others had a fibrous wall. The contents of the cyst was a granular or mucoid material and some desquamated cells. Diagnosis: Multilocular ovarian cyst. The chemical examination showed the cyst to be formed of four cavities. The largest cavity contained a thick opaque, slimy fluid of specific gravity 0.014. Smaller cavities contained a similar fluid of greater concentration. Specific gravity 1.045. A guineapig was injected with ten c. c. of the fluid of the larger and smaller cavities. Bacteriological studies were run on the contents of the largest nd on one of the smaller.

	I	II		I	II		I	II

			Smaller.					
	—	—		—	—		—	—

The pigs showed no ill effect subsequent to the injection, being down to the original weight upon the following day. No rise of temperature was noted in either case. The weight of the pigs increased steadily daily.

The cystic contents were of a sticky, ropy, mucilaginous nature. It gave no precipitate with acetic acid. Upon dilution with water and the subsequent addition of a little acetic acid, a slight precipitate was obtained, which was readily soluble upon the addition of a few drops of ten per cent. sodium chloride, as well as in a slight excess of the dilute acid and in dilute alkali.

When the original fluid was boiled, diluted, and acetic acid added, it turned milky, but no flocking out occurred. Upon coagulation after the addition of two volumes of five per cent. sodium chloride, flocking out occurred and the filtrate obtained from this was slightly turbid, analogous to a weak solution of glycogen. Tests for glycogen were negative. This filtrate was concentrated greatly, precipitated with large excess of alcohol. The resulting precipitate, which gave the protein color reactions, was hydrolyzed, giving a substance which reduced Fehling's solution.

Salting out experiments. The original cystic contents gave no precipitate on saturating with sodium chloride in substance. The acidification of this solution with acetic acid called forth a copious precipitate, which was soluble in water. The fluid treated with an equal volume of saturated ammonium sulphate solution gave a very slimy, mucilaginous, gummy precipitate. The filtrate from this precipitation was watery, the fluid being deprived entirely of its viscidity by the removal of the globulin precipitated by half saturation with ammonium sulphate. Complete saturation of this filtrate gave but a slight precipitate, as did the addition of a large volume of alcohol. The protein obtained by half saturation with ammonium sulphate and by coagulation gave no reducing substance upon hydrolysis. A reducing substance was obtained only from the hydrolysis of the substance, not precipitated by half saturation with ammonium sulphate, but precipitated by alcohol. This gave a characteristic dextrosazone.

ANALYSIS (PARTS PER 1,000).

	Contents of large cavity.	Contents of smaller cavity.
H_2O	955	852
Total solids	45	148
Ash	9.4	16

The substance, not coagulated by heat but precipitated by alcohol, and which represented but a trace of the entire protein content, gave all the protein color tests, was insoluble in water, soluble in dilute alkalies, from which it was not precipitated upon the addition of acid.

Cyst III (laboratory No. 7733) occurred in patient, H. C. twenty-three years of age, white, married, housewife, born in United States. The patient was admitted to Jefferson Hospital with a history of delayed menstruation of one week's duration and with bleeding from vagina for eighteen days. There was tenderness over right lower quadrant of abdomen. The operation, performed by Professor E. E. Montgomery, revealed a right sided ruptured ectopic gestation sac and a left ovarian cyst. The patient made an uneventful recovery.

The specimen, as described by the laboratory report, consisted of three parts. One was a tube which measured 12 cm. in length and at its widest portion 3 cm. in diameter.

[1]The authors are under obligations to Dr. P. B. Bland, for suggestions.

At junction of outer and middle thirds there was a rupture in tubal wall one cm. in diameter. Second part of specimen was a mass of clotted blood. Third part was a cyst measuring 10 by 8 by 8 cm. The capsule was thin and contents a thin watery fluid. Part of ovary was spread out over the capsule. Diagnosis: Simple ovarian cyst, chronic catarrhal salpingitis, ruptured tubal gestation sac.

The chemical analysis showed the cyst to contain 125 c. c. of serous fluid. Injection into animals showed no symptoms after injection.

BACTERIOLOGICAL STUDIES.

	I	II		I	II		I	II
Agar colonies,	—	—	Gel.,	—	—	Bouillon,	—	—
	0	0		0	0		0	0

Cyst IV (laboratory No. 7748) was removed from patient, A. H., twenty-five years of age, married, white, American. The patient complained of pain in right inguinal region for several months prior to admission to St. Agnes Hospital. Operation performed by Dr. H. J. Hartz. Through a median abdominal incision, cyst of right ovary with associated tube was removed. Patient made good recovery. The laboratory report described the specimen to weigh 200 grams. The ovary was taken up by a cyst which measured 6 cm. in diameter, with the capsule of moderate thickness. The tubal walls were thin and spread out over cyst. Incision showed cyst to be formed of several compartments, some containing blood intermixed with cyst contents. Microscopical sections revealed small follicular cysts and forming part of the smooth wall of a larger cyst. Diagnosis: Multilocular ovarian cyst. The chemical analysis showed contents of fifteen c. c. of a bloody fluid. Three c. c. of the contents were injected into each of two guineapigs, which showed no reaction.

	I	II		I	II		I	II
Agar colonies,	—	—	Gel.,	—	—	Bouillon,	—	—
	0	0		0	0		0	0

Cyst V (laboratory No. 7765). The patient, A. F., thirty-seven years of age, married, housewife, white, born in England, was admitted to Jefferson Hospital, complaining of irregular pains in lower abdomen of seven years' duration; the pain more pronounced during menstruation. Operation by Dr. P. B. Bland for relaxed pelvic floor and repair of cervix. Abdomen was opened and small cyst and appendix removed. The pathological report described specimen as a globular cyst, 6 cm. in diameter. The surface was of a glistening gray color; thin walls with mottling with dark areas beneath surface contained numerous small cysts. The microscope showed sections of ovary with a moderate increase of connective tissue and numerous small smooth walled cysts, some of them lined by flattened epithelium. Diagnosis: Multiple follicular cyst of ovary. The chemical analysis showed the small unilocular cyst containing about 75 c. c. of serous fluid. Guineapigs showed no rise in temperature and no loss of weight.

BACTERIOLOGICAL STUDIES.

	I	II		I	II		I	II
Agar colonies,	—	—	Gel.,	—	—	Bouillon,	—	—
	0	0		0	0		0	0

Cyst VI (laboratory No. 7774) occurred in patient, C. A., thirty years of age, who was admitted to Jefferson Hospital, complaining of increasing pain of one month's duration in lower left abdomen. For past week the pain was quite severe. The operation, performed by Dr. P. B. Bland, consisted in removal of a large ovarian cyst; patient making a good recovery. The laboratory described the specimen as weighing 4 kilos, 800 grams; measures 30 by 22 by 20 cm. The surface was embossed by numerous variously sized elevations. Beneath capsule were numerous small cysts. Incision into mass showed one large sac containing an opaque thick fluid; the lining was roughened in places and showed a few nodulations which were spongy and contained a thick whitish gray gelatinlike fluid. Several smaller cysts of same character as above described sac comprised the mass. Microscopical sections showed a succession of cysts lined by columnar epithelium. Some were separated by thin bands of connective tissue, others by broad masses containing gland structures. In many of the cysts were papillary projections, mainly small. The cysts contained pale staining, slight granular material, and desquamated cells of ovary. Diagnosis: Papillary cystadenoma of ovary.

The chemical analysis showed the large multilocular cyst containing 3,400 c. c. of a very opaque viscid fluid, specific gravity 1.018. The injected guineapigs showed no subsequent effects of the infection. No rise of temperature was noted, and the original weight was reestablished upon ensuing day.

BACTERIOLOGICAL STUDIES.

	I	II		I	II		I	II
Agar colonies,	—	—	Gel.,	—	—	Bouillon,	—	—
	0	0		0	0		0	0

Staphylococcus albus colonies were present upon one plate—undoubtedly a contamination.

Chemical examination. Coagulated protein, filtered, evaporated filtrate, precipitated a small amount of protein substance with large excess of alcohol. The contained protein substance gave a very faint opalescence to the filtrate. The substance precipitated by alcohol gave a reducing substance upon hydrolysis.

CONCLUSIONS.

The contents of the different cysts were found to be sterile in each case.

The cysts examined showed no toxicity, regardless of the nature of their contents. No rise of temperature nor loss in weight was noted in any guineapig after injection. The animals were killed about twelve weeks after injection, and no lesions could be determined macroscopically.

In two cases the physical nature of the contents was mucilaginous in the extreme, having the physical appearance of a mucin substance. That this property was due to the globulin content and not to a mucin substance was shown by the precipitation properties and coagulability of the substance in question accompanied by the lack of viscosity in the resulting filtrates. A slight amount of pseudomucin was obtained in each case, but the trace present could in no way account for the physical characteristics of the contents.

DEMENTIA PRÆCOX.*

The Condition in the Light of Modern Conception,

By Morris J. Karpas, M. D.,
New York,
Chief of Clinic, Neurological Institute; Clinical Instructor in Neurology, Cornell University; Formerly Assistant Resident Alienist, Bellevue Hospital.

Of all chronic mental diseases, dementia præcox forms one of the most important types, and indeed it embraces a high constituent of the entire insane population. Because of its relative frequency and poor prognostication dementia præcox has become an object of careful study and inquiry, and neither time nor effort has been spared in attempting to establish the underlying pathogenesis of this affection. Various scientific activities have been undertaken by different investigators from many depart-

*Read before the Eastern Medical Society, March 10, 1916.

ments of medical sciences to solve this intricate and difficult problem. For instance, biochemical studies have so far given no satisfactory explanation for this peculiar abnormal mental condition. Likewise observation along the lines of internal secretion have proved unsuccessful. In this connection it is interesting to call attention to the fact that Abderhalden's researches have shed no light upon the true nature and genesis of dementia præcox. Persistent psychological investigations and anatomical studies have been carried on with great vigor, but with only partial success. It would be important to discuss briefly two important views.

According to Kraepelin, dementia præcox is of an organic nature. Moreover, he goes so far as to maintain that the psychotic manifestations can be correlated with disturbance of the functional areas in the brain. In the last edition of his book, *Psychiatrie,* he attempts to outline the anatomicopathological picture. He finds that the lesion is invariably in the second and third layers of the cerebral cortex. Furthermore, the usual site of predilection is in the region of the frontal lobes, central convolution, and temporal lobes. He describes cases in which sclerosis of the nerve cells, formation of lipoid substances in the reticular connective tissue, and increase of glia tissue were found. In fact, he differentiates two anatomical groups. The first is characterized by cell alteration, formation of disintegrating substances, and hyperplasia of glia, especially with the appearance of ameboid glia cells. In the second type we find destruction of cells and fibres, necrosis and retrogressive manifestations of nervous tissue and glia with formation of fat and pigment.

On the strength of these pathological findings in a few isolated cases, Kraepelin attempts to give anatomical localization for various symptoms in dementia præcox. For instance, the motor and volitional disturbances he places in the region of the anterior central convolution. Incoherence of speech with formation of new words and auditory hallucinations he ascribes to the temporal lobes. In dementia præcox judgment and critical judgment, creative energy, especially the ability for higher appreciation of knowledge and understanding are impaired, and for these symptoms the small celled layers of the frontal lobes are said to be responsible.

Another invaluable conception of the genesis and nature of dementia præcox is advanced by Bleuler, which is worthy of our careful and thoughtful consideration. This observer emphasizes both the constitutional and psychogenic factors. The former expresses itself in primary symptoms which are association disturbances in the trend of thought, stuporous states, acute episodes of depression and elation, and some somatic abnormalities, such as inequality of pupils, tremors, and vasomotor disturbances. Bleuler admits, however, that the pathological foundation of the constitutional disorder is not well defined, but he vaguely hints at the idea of faulty metabolism and the possibility of an organic condition. One point must be borne in mind—that he admits a certain diathesis in dementia præcox which in this country has been fully accentuated and defined by such careful observers as Meyer and Hoch. According to these investigators, dementia præcox develops in a peculiar type of personality which is termed "shut in." Such a mental make-up can be demonstrated in a large majority of cases, particularly where the anamnestic data are reliable.

The active psychotic manifestations which Bleuler calls secondary symptoms are as a rule controlled by definite psychological factors. For instance, a patient reacts to auditory hallucinations telling her that her illegitimate son is a Messiah, or another imagines herself to be the queen of the world because she was born of a family from which usually kings originate and that King Edward is her great-grandfather, or again another is imbued with the idea that she is the object of incessant persecutions and annoyances because a certain prominent politician whose actual acquaintance she has never made, is desirous of marrying her. Such cases illustrate pretty conclusively that somatic factors alone are not sufficient to bring forth such psychological phenomena, but are indeed traceable to a certain mental undercurrent in the unconscious.

In this country, Professor Adolf Meyer laid considerable stress on the psychic factors in dementia præcox and maintained that "habit disorganization" is an important feature in the production of this mental disorder.

From the objective standpoint, dementia præcox is a chronic dementing disease in which there is affection of emotions and volition. The emotional disturbance usually manifests itself in indifference and apathy with considerable incoordination between thought content and affect. The volitional abnormalities express themselves in impulsive acts and automatic states. In addition the personality becomes distorted to such an extent as to cause maladaptation. In a normal personality the various individual mental forces are harmoniously adjusted, but in dementia præcox they are disorganized and dissociated. In other words, the instincts, emotions, volition, and intelligence are not in harmony or mutual association and union to coordinate constructive mental energy. The incoordination of this type of personality is analogous to that exhibited in the fable of the crane, the crab, and the pike. It will be recalled that these three animals undertook to move a loaded wagon to a certain destination; the crane tried to fly with it to the sky, the crab drew it to the side, and the pike attempted to swim with it to the ocean. Such is the state of the personality in dementia præcox—*in brief, a dissociation of psychic activities, particularly affecting the emotional and instinctive phases of mental life.*

Upon this pathological mental soil psychotic symptoms of varied kinds may develop, and the clinical picture may assume various forms. In some instances, a dementing process without psychotic manifestations is in the foreground; in other cases a hebephrenic symptom complex may dominate the disease picture; in other conditions simple depressive and stuporous dementing states may be noted; still others may exhibit a depressive dementia with delusional ideas; circular, agitated, and periodical forms may also occur; paranoid and catatonic coloring in dementia præcox is relatively frequent; in the progressive and later dementing stages, speech disturbances in the sense of marked incoherence,

etc. (schizophasic), characterize the clinical display.

Considerable stress must be laid on the fact that the mental deterioration in dementia præcox is purely of an emotional type associated with volitional disturbances. Intellectual symptoms, in the sense of memory defect and loss of school knowledge and grasp, are not of primary origin. As the disease progresses and emotional sluggishness becomes more and more pronounced, intellectual symptoms may make their appearance. It is worthy of emphasis that the diagnosis of dementia præcox is not made on one symptom alone, but the entire mental reaction must be taken into consideration.

The underlying etiological factors are not known, but as Meyer truly remarks: "The constitutional make-up counts for a great deal, but not in the vague sense of heredity and degeneracy merely. There is more to be had in the study of deterioration of the habits and undermining of instincts and their somatic components."

The actual therapeutic outlook is rather grave. While psychanalysis has done a great deal toward helping us to understand various abnormal mental phenomena, as a therapeutic method in dementia præcox it has actually failed in the well developed cases. This is due to the fact that the infantile fixations and the psychosexual life in dementia præcox are not of such plasticity as in psychoneuroses, and, moreover, the peculiar type of mental deterioration is antagonistic to analytic procedure. It must be also borne in mind that the delusions, hallucinations, and other psychotic symptoms are the patient's means of adjusting his morbid situation, and, in removing them, the patient's condition becomes worse because he was deprived of methods he employed at adaptation.

Reeducational methods can be applied in some cases with apparent advantage, not, however, with the hope of bringing about complete mental restoration, but rather to arrest the process of disease to such an extent as to enable the patient to adjust himself to a certain environmental level. Work along this line has been done in Manhattan State Hospital under the wise management of Dr. William V. Mabon, to whom I am greatly indebted for permission to quote from his unpublished paper[1]:

> In certain cases which are sent to hospitals reeducational methods are of value in arresting somewhat the progress of the psychosis, and enabling a better adjustment by the patient to his surroundings.
>
> At the Manhattan State Hospital twelve classes in the female department have been established in arts and crafts which are attended by about 200 patients. These classes are not only for the dementia præcox, but for some of the recoverable forms of the psychoses. We find that in some cases of dementia præcox this treatment has a tendency to improve somewhat the conduct and habits. We established, in 1913, a special class for the reeducation and habit training of the dementia præcox male patients. Three groups were arranged, one almost kindergarten in character, for the very deteriorated and untidy cases, one in clay modelling for less deteriorated cases, and a class in art work in some of the simpler forms of manual occupation. If improvement was shown in the lowest grade, promotion to a higher grade followed. In a number of cases considerable improvement has been obtained in habits and behavior.

The great hope of actual therapy lies in prophylaxis. Since it is well known that in dementia præcox there is a peculiar type of personality which exists prior to the development of the active disease, definite steps may be taken to prevent the final mental upset. These individuals are really *mental clams;* they live in their own shell; the real world is a source of little interest or inspiration to them; all difficult problems are solved, not in reality but in their fantasy; they are self absorbed; extremely selfish, and seclusive. In other words, their mental adjustment is purely autoerotic. When they are forced to come in contact with actual reality, a definite break in adaptation may frequently occur which determines the mental upset. If such constitutional traits are detected in the early stage of mental plasticity, considerable good may be done for these unfortunate patients. Here psychanalysis is invaluable in aiding them to form healthy mental habits and encouraging them to look upon the actual world, not in a fantastic way, but from the point of view of reality. In conclusion, the wise words of Adolf Meyer may be aptly quoted:

> We stand here at the beginning of a change which will make psychiatry interesting to the family physician and practitioner. As long as consumption was the leading concept of the dreaded condition of tuberculosis, its recognition very often came too late to make therapeutics tell. If dementia is the leading concept of a disorder, its recognition is the declaration of bankruptcy. Today the physician thinks in terms of tuberculous infection, in terms of what favors its development or suppression; and long before "consumption" comes to one's mind, the right principle of action is at hand—the change of habits of breathing poor air, of physical and mental ventilation, etc. In the same way a knowledge of the working factors of dementia præcox will put us into a position of action, of habit training, and of regulation of mental and physical hygiene, as long as the possible "mental consumption" is merely a perspective and not an accomplished fact. To be sure, the conditions are not as simple as with an infectious process. The balancing of mental metabolism and its influence on the vegetative mechanisms can miscarry in many ways. The general principle is that many individuals cannot afford to count on unlimited elasticity in the habitual use of certain habits of adjustment, that instincts will be undermined by persistent misapplication, and the delicate balance of mental adjustment and of its material substratum must largely depend on a maintainance of sound instinct and reaction type.

[1] This is in part Doctor Mabon's discussion of the author's paper at the Eastern Medical Society, March 10, 1916.

AUTOSEROTHERAPY.

By Francis Huber, M. D.,
New York,
Professor of Clinical Medicine, College of Physicians and Surgeons, Columbia University; Visiting Physician, Gouverneur Hospital; Etc.

In the management of serous pleurisy, particularly in hospital practice, it is not an infrequent experience to find a patient make a rapid recovery after an exploratory puncture and the withdrawal of a small amount of fluid, not exceeding three to ten c. c. This has been observed, even, in cases in which the effusion was sufficient to obliterate the Skoda resonance on the affected side. It is a well recognized fact that the removal of large quantities, eight ounces and more, by relieving the pressure on the lymph vessels, favors subsequent absorption. An interesting question now arises: How are we to explain the cures in the cases referred to? The removal of a few c. c. cannot materially relieve or influence the pressure on the absorbents.

In the abstract of an article by Marcon, Autoseropathy (New York Medical Journal, November 6, 1909), the results of autoserotherapy resorted to by him and Tchigoeff are briefly presented. An exploratory puncture is made in every case of pleural effusion, about two c. c. being taken off. If the fluid is pale yellow, transparent, or even somewhat hemorrhagic, the Gilbert treatment, advocated in 1894, is applied, that is, the fluid is reinjected without entirely withdrawing the needle direct into the subcutaneous tissue, so that it is not necessary to make two punctures. The puncture is then covered with sterilized gauze and the patient is told to rest. A second injection, if necessary, is given after the lapse of a week. The method has absolutely no antituberculous action. It is surmised that the injection produces a pleuritic antibody, which causes the rapid cure. Carried out under the usual aseptic precautions, no local or general ill effects follow. Occasionally we meet with a case in which the fluid is turbid and has a decided odor; under such conditions the method is not to be resorted to. In the three instances which have come under my observation, the fetid penetrating odor was noticed at the time of aspiration, when the piston was drawn up to obtain some fluid. The odor was evident before the needle was removed. In this type, severe infection of the superficial and deeper structures has followed a simple exploratory puncture in spite of all precautions. The treatment is of necessity surgical and does not concern us here.

Such fetid effusion is probably due to a local gangrene of a superficial portion of the lung, and as the process has not involved a bronchus, fetid expectoration and odor are absent. The constitutional symptoms may not be suggestive, the true state may escape us until revealed by the exploratory puncture or a communication is established with a bronchus. In either case the characteristic odor clears up the diagnosis.

Rudisch, speaking of autoserotherapy in chronic pleurisy with effusion, cites three cases treated by him. He believes that the results warrant a more extended use of this form of treatment. Doctor Rudisch also reports a case with x ray plates of lymphosarcoma of the mediastinum, in which striking results were shown, not only in the improvement of the general condition, but also in the marked diminution in the size of the tumor (*Med. Rec.*, April 8, 1911, p. 650). Others have presented equally favorable reports.

Now as to a possible and plausible explanation of the problem presented in the cases, in which a cure follows a simple exploratory puncture and the withdrawal of a few c. c. of fluid—may we not unintentionally have resorted to autoserotherapy? A small amount of fluid which is subsequently absorbed, escaping into the tissues, through the small wound made by the exploring needle, accomplishes the same purpose as though it had been injected. In thin patients, particularly in children, fluid frequently escapes externally, being forced out by intrathoracic pressure through the track left by the needle after exploratory puncture or aspiration. In empyema operations performed one or two days after an exploratory puncture, a small amount of pus is not infrequently found external to the intercostals or may be seen oozing through the minute puncture, when the deeper structures are incised, preparatory to opening the pleura.

About six years ago, while employing the Murphy method in empyema, a two per cent. formaldehyde solution in glycerin was injected into the pleural cavity after aspirating as much of the pus as possible, the needle not being disturbed. Later on, when a radical operation was done, the deeper tissues were found infiltrated, brawny and hard, a condition unquestionably due to the action of the solution escaping from the pleural cavity through the puncture. A similar leakage is often observed in serous pleurisy when only a part of the fluid is taken away.

Those who have done a number of lumbar punctures have frequently observed that an escape of cerebrospinal fluid follows the withdrawal of the needle. Slight pressure and a simple dressing prevent any further flow.

To cite an analogous condition in which the fluid escapes into the subcutaneous tissues through a needle puncture, I might refer to what is seen in superficial tissues. Many of the older practitioners may recall a plan of treatment formerly employed to cure hydrocele. The scrotal tissues having been made tense, a surgical needle was thrust into the sac, the needle was withdrawn, pressure removed, and the fluid allowed to escape into the subcutaneous connective tissues. It was quickly absorbed and in a number of cases, particularly in children, a cure followed.

If the small amount injected in the Gilbert method is so effective, may we not logically infer that a similar favorable action may take place after exploratory puncture, in which, as has been shown above, more or less serous fluid escapes into the tissues through the puncture in the costal pleura, and is subsequently absorbed? The more slowly the needle is withdrawn, the greater the tendency to oozing of the serous fluid through the puncture in the costal pleura. No doubt, some additional fluid does escape into the deeper tissues in the Gilbert method. If the view is correct, more antibodies are formed to favor a cure.

Unconsciously we may have practised autoserotherapy—providing the system with antibodies or some ferment substance, thereby tending to facilitate the absorption of the serous contents of the pleural cavity.

THE CLINICAL SIGNIFICANCE OF A GASTRIC ANALYSIS.*

Second Communication;

By Louis Winfield Kohn, M. D.

Philadelphia,

Röntgenologist, Allegheny General Hospital; Dermatologist and Röntgenologist, Pittsburgh, Columbia, and St. Francis Hospitals.

A time there was, "when we travelled through a region of smooth and idle dreams," but now we seem to be "arriving on the confines where daylight and truth meet us with a clear dawn, representing to our view, though at a far distance, true colors, and shapes." How adequately these lines

*Read before the Pittsburgh Academy of Medicine, February 29, 1916.

apply to our knowledge of a gastric analysis! Owing to an increase in the mind's understanding, we are already come to that stage where the true significance of the gastric findings is being better appreciated, where we are less prone to entertain false ideas and less apt to jump to incorrect conclusions.

In a paper preceding this has been discussed the significance of the fasting stomach findings, while in this paper the findings in examination of the test breakfast contents will be reflected upon.

Leube (1) first studied the supposedly empty stomach at a time when he normally expected to find it empty. His object was to determine the time of digestion and the strength of the gastric secretion at certain definite periods after digestion was supposed to have taken place, but the reasons which he advanced for so conducting the analysis have since been declared illogical, and now the contents are studied at a time when secretory activity is expected to be greatest, viz., at the height of digestion, about fifty minutes to one hour after a test breakfast. There was a time when an examination of the test breakfast contents was altogether depended upon for information relating to the time of digestion, the effect upon the foods, and the motor powers, but now we gain more accurate knowledge of these properties through the additional employment of other methods such as the fasting stomach test, fluoroscopy, and Röntgenography. These other innovations are of inestimable value in enabling the diagnostician to arrive at a more correct interpretation of the significance of the acidity findings in cases where these figures seem puzzling.

In our quest for information regarding the powers of the stomach, it is unfortunate that only comparative results can be obtained, namely, results to be compared with those average results acquired in a normal stomach. For this reason, we make use of a test meal consisting of ordinary food, to which the stomach is accustomed. There is a great divergence of opinion as to which test meal should be employed. Many have been advocated for this purpose, but the one most commonly used is the Ewald-Boas test breakfast, which as often administered consists of 200 to 250 c. c. (about a glassful) of water or tea and forty grams (about one rather large slice) of bread. This meal is usually administered in the morning soon after the fasting stomach has been relieved of its contents. The patient should slowly and gently masticate the bread and imbibe the water; the entire operation should not comprise more than five minutes or thereabouts. About fifty minutes to one hour later, the stomach contents are removed by aspiration, for it is only by aspiration that an approximately correct idea of the quantity of the contents is attained.

The methods by which a very accurate conception of the amount of the gastric contents is attainable are those of either Mathieu-Remond (2) or Strauss (3), but since for practical purposes we can through ordinary aspiration, properly performed, acquire an approximate idea of the quantity of residue which is of importance in the determination of the significance of the acidity degree, we do not make use of these methods to any great extent. The "quantity" of test breakfast residue may give information of value relating to gastric motility and to the extent of dilution to which the contents are subjected. Often the information regarding motor power is corroborative in nature, substantiating the more or less grave disturbance not seldom found by the fasting stomach test, but there are times when an increased quantity may suggest minor forms of motoric insufficiency, while a diminution or absence would portend a more or less hypermotile state. A large quantity of contents may also be found in cases of hypersecretion, whether purely digestive or continuous in type, but it is the physical character of the contents and their chemical nature as well that must be considered before making such a decision. From twenty to seventy-five c. c. is regarded a normal quantity for test breakfast contents, and when amounts of greater or lesser degree occur, a probability of disturbance in some form or other suggests itself. A smaller quantity or absence impels us to think of a possible associated hypermotility, which may have some one or more definite underlying causes and may be present in achylia, cancer of the stomach body, perigastric adhesions which keep the pylorus patent, and in conditions the result of reflex irritation from other sources. A larger amount may appear in such cases as hypersecretion, atony, and obstructions of organic or spastic type.

Authorities differ regarding the most appropriate time for removing the test breakfast contents, but nearly all select that point at which digestion is supposed to be at its acme. Some allege for this point the thirty minute limit; others the forty-five minute limit; still others the sixty and seventy-five minute limits. Some again, since fractional methods are in vogue, hold that no definitely fixed period can be designated. However, judging from what limited experience the author has had, as well as from the views held by others of vast experience, he suggests that if a time limit is desired, it should be from fifty to sixty minutes.

A further study of the appearance and consistence of the residue conveys additional information of value. For instance, where we have excessive fluid constituents, a hypersecretion may be present unless this fluid material consists mainly of mucus, in which case it may mean a mucoid gastritis, but the chances are also, that the quantity of fluid in the former instance will be much greater than in the latter. Excessive solid constituents may denote an atony of mild or grave form, dilatation, ptosis, or an obstruction of some form or other. When a sufficient or excessive amount of acid secretion exists, we usually find the bread in a fine, well divided, and mushy state, while in cases of subacidity or hyposecretion the bread particles appear to be poorly divided, coarse, and clumplike. In cases of sufficient acid concentration, salivary digestion in the stomach without a doubt is interrupted early in many instances, while in the subacid cases salivary digestion probably continues for a longer period. The physical subdivision, however, to which the bread is subjected, excluding the process of mechanics or mastication and the mechanical effect of gastric muscular contraction, is un-

questionably due to the chemical process or dissolution of the bread framework or gluten by the gastric secretion. After the bread has been soaked in this gastric juice for some time, a disintegration of the bread particles occurs owing to the chemical dissolution of the gluten or bread framework, as a result of which the starch granules are liberated. Thus we have the finely divided and mushy appearing residue. In subacid or achylia cases, this chemical activity is deficient or at times probably lacking, owing to the inactivity or absence of the pepsin, as a result of which the gluten or albuminous substance of which the bread framework consists, is not properly disposed of, and for which reason also coarse particles or bread clumps appear. In these cases, however, salivary digestion may be more lengthy and more complete because of the inadequate or absent acid medium, which fact favors salivary activity. Thus the salivary secretion, which has gained access to the interior of the many starch cells through the avenues created for it by the break in continuity of the starch capsules, as a result of mechanical crushing by the teeth or following the bursting of the starch cells after swelling due to their taking up water, or by the saliva permeating the intact capsular wall itself, may continue its diastatic activity for a longer period. Where the test breakfast contents are entirely absent, or where only a small quantity of mucus or residue is present, we should expect a hypermotility associated with either an achylia of primary or secondary form, or with a tumor of the body of the stomach either benign or malignant in nature. Further investigation, however, is necessary to verify such an opinion. Where definite obstruction exists at the outlet of the stomach, the contents, upon standing, usually present three characteristic layers, a lowermost solid layer consisting of the solid elements (bread particles), a middle cloudy layer of fluid, and an upper foamy or gaseous layer the result of fermentative processes. In those cases where the fasting stomach contents, or if not sought, the test breakfast contents, should exhibit a liquid butter appearance, or if upon standing its upper layer looks like a soft crust of fat, an intolerance of fat is very suggestive and usually points to a chronic duodenitis with which a pancreatitis is associated, and often syphilitic in origin.

The color of the test breakfast contents is usually pale yellow or muddy gray, as is naturally expected of a bread pap mixture. When the precipitate has settled to the bottom, the fluid will appear to be more or less colorless and either transparent or cloudy. At times, just as in the fasting stomach contents, the color may be green or yellow because of the bile pigments, red or brown because of blood, etc., depending upon the condition present.

The odor is most often paplike, but may at times be distinctly sour or even odorless. When yeast fermentation occurs, there is a musty odor. When albuminous fermentation or putrefaction occurs, a hydrogen sulphide odor is very manifest. Where butyric acid appears, the rancid butter odor is evident. Where carcinoma exists, a very fetid odor is apparent. In intestinal occlusion or obstruction low down, a fecal or offensive odor will usually be present. The odor depends greatly upon the condition present, being very offensive in obstructive conditions.

The test breakfast contents are not subjected to a microscopical examination as frequently as formerly was the custom, because almost all the information anticipated by this means is acquired by an examination of the fasting stomach contents. This is done, however, for routine sake and will give some information relating to the degree of carbohydrate digestion. In cases where starch digestion has been poor, the starch cells appear mainly large, confluent, stain deeply blue with iodine, and are present as a rule in great quantity or concentration. In cases where starch digestion has occurred to a high degree, the starch cells or granules seem to be finer, not confluent but rather isolate, not in such great concentration, and stain a paler blue or light brown or do not stain at all. Ordinarily, also, isolated yeast cells in small proportion are present, and where active fermentation occurs, the sprouting variety are seen in large amounts. When mucus, bacteria, and epithelial cells are noted, they have practically the same significance as in the fasting contents. Rarely will such material evidence present itself in the test breakfast contents as is usually found in the fasting contents of a case of pyloric obstruction unless the contents had not been entirely removed from the fasting stomach. Ordinarily, the test breakfast contents will show nothing beyond the presence of numerous starch granules, a varying quantity of yeast cells, more or less mucus, and some bacteria of unimportance or unknown significance. When food remains such as fat, muscle fibres, vegetable cells, and organisms like the Opler-Boas bacilli and sarcinæ are found, they undoubtedly result because of their incomplete removal from the fasting stomach and have a significance similar to that when found in the fasting stomach. Microscopic examination is a means for studying what cannot be seen otherwise as well as for studying in detail what cannot be so determined macroscopically, and as a rule only slightly enhances the already acquired information. From the viewpoint of scientific principle, it is good practice to incorporate this method in our routine examination.

The chemical examination of the test breakfast contents is the most important test to which this material can be subjected. By this means we acquire valuable information pertaining to the digestive powers of the stomach. The degree of acidity, as ordinarily expressed, means very little unless the total amount of fluid contents is approximately if not entirely known. The varying amount of fluid contents unquestionably influences inversely the degree of acidity or concentration, viz., the greater the quantity of fluid content, the less the degree of acidity and *vice versa*. If this fact is borne in mind, we shall no doubt better appreciate the significance of gastric chemistry.

Since it is held that the different gastric ferments act only in the presence of free hydrochloric acid, the digestive power may naturally be appreciated by a knowledge of the acidity status. The total acidity is the chief index, therefore, to the acquisition of information relative to the digestive power,

because even though it actually consists of the free and combined acid, it virtually communicates to us the degree of available free acid that had been thrown out into the stomach, of which a certain portion has combined chemically with the protein substances of the food. Ordinarily, the free acid of the contents is represented by the free uncombined hydrochloric acid, but there are times when organic acids, such as lactic, acetic, and butyric, are present in moderate amount. These organic acids are almost always associated with fermentative processes such as occur in pyloric obstruction, atony, and dilatation, but the symptoms of the case with the odor and macroscopic appearance of the gastric contents will usually foretell the presence of these abnormal acids, especially if in large quantity. The acid which has bound itself chemically to the protein substances is known as the combined acid. A small amount of the combined acid in the gastric contents also consists of acid salts, such as the dihydrogen phosphate. So, therefore, from what has above been enumerated, it can be readily seen that the total acidity comprises the free hydrochloric acid, what little organic acids are present, combined hydrochloric acid and acid salts, of which for our information regarding digestive power the total quantity of hydrochloric acid, free and combined, is sufficient.

As has already been stated, however, an approximate idea of the amount of gastric contents is essential before we formulate a definite opinion regarding digestive power. There can be no fixed data regarding the acidity limits in normal cases, since it is known that, just as the acidity varies in different supposedly normal beings, so also the quantitative evacuation of gastric contents probably varies, and it matters not how slight the variation may be, it nevertheless has its direct bearing. We cannot safely assume a steady, uniform, equal in quantity evacuation, in jerklike manner, of gastric contents, because we are dealing with a nervous mechanism which is a complex factor, not well understood, and known to act often in an erratic manner. Since we have no assurance of a uniform evacuation or of a uniform gastric secretion, and even if one or the other was uniform, it can readily be perceived how difficult or how erroneous it is to ascribe certain definite acidity degrees to a supposed normal gastric fluid for future use as an arbitrary standard. We can do only one thing, therefore, in this respect to be fair with ourselves, and that is to give wide limits wherein most often the acidity of the normal contents will fall. The author, from his experience, feels constrained to conclude that the total acidity of the gastric contents in most normal cases (no complaint to offer) will at the fifty to sixty minute limit vary anywhere from forty-five to seventy-five degrees, while the free acid may vary from twenty to fifty degrees, although even here exceptions beyond either extreme may be noted. The principle of dilution, which is controlled by gastric motility and by the degree of gastric secretory stimulation, is a foremost factor in the creation of the different gastric acidities.

The acidities that obtain, as in the relation existing between cause and effect, correspond to the latter, and at once seem to inform the mind of the possible causes of their production. For instance, where a fluid showing a high degree of acidity presents itself, we can think of one or more causative factors. First of all, a disturbance involving gastric secretion and gastric motility, either separately or jointly, suggests itself. Of course, gastric sensibility may contribute forcibly toward the production of a derangement of either of these functions. If upon further investigation, we should find a small quantity of gastric fluid associated with this increased degree of acidity, we are very apt to explain this by a rapid evacuation (hypermotility) of contents from the stomach and the comparatively small concentrated portion left. On the other hand, cases that present a large quantity of gastric fluid associated with increased acidity can often be explained by a prolonged and increased glandular action with a resulting pylorospasm, which two factors contribute to the accumulation of highly acid fluids. A highly acid fluid in large quantity may also possibly arise from an increased secretory activity with a concomitant atony of the gastric musculature, in which case the accumulation of fluid would be due to a lack of propulsive power on the part of the stomach musculature, while the true acidity would follow from the increased glandular outflow. Where we have a fluid of high acidity and of an approximately normal quantity, a hyperchlorhydria or either of the preceding causes may be associated therewith, but a detailed study of the quantity and quality of the constituents of the acquired contents must in all cases be resorted to before coming to approximately reliable conclusions. Only by so doing can we attain a true idea of the degree of dilution or concentration to which the gastric contents have been subjected, and so it is with gastric contents at any time, irrespective of acidity degree. We must inquire into the immediate causes of the production of this acidity as just explained, before we dare seek the original or true underlying causes, such as ulcer, appendicitis, new growths, myasthenia gastrica, etc. It is only natural, we might say second nature, to suggest a diagnosis from inference after the immediate causes are available. "Suggest a diagnosis" is very befitting here, for it is only after every other available means is exhausted that we can with a degree of certitude make a diagnosis.

Let us now consider the subject of low acidity degree. Here, again, the principle of dilution which, as already stated, is governed by the degree of secretion and motility, comes to the foreground for consideration. When a large quantity of gastric contents has a low acidity degree, it occurs to our minds that an insufficient musculature has interfered with the onward propulsion of our test meal, thus diluting the contents and producing a subacid state. When a low acidity concomitant with a smaller quantity of material presents itself, we are prone to suspect a deficiency of the gastric secretion. When a quantity approximating the normal exists with a subacidity, we are in somewhat of a quandary, but we may suspect a deficiency, of variable degree, involving gastric secretion and motility, either separately or jointly, probably more depressing upon the former. In these cases of subacidity, however, we

must not forget the role played by the duodenal fluid where regurgitation has occurred, for we know that this regurgitant material, aside from its diluting tendency, will tend to neutralize or lower the acidity of the contents. Here, again, with this knowledge at hand, we are in a better position to suggest a diagnosis to ourselves, as chronic gastritis, myasthenia gastrica, ptosis with atony, duodenal occlusion, etc., and then after corroboration from other sources, clinch the diagnosis.

To cases where the acidity is of exceptionally low degree, in which the total acidity amounts at the highest to 10° or thereabout, and where no free acid exists, the name "achylia" is applied because of the usual absence in these cases of the gastric ferments. The amount of fluid acquired in these cases is almost invariably very small and often consists mainly of mucus. There is as a rule an atrophic mucous lining devoid of secretory elements in these cases, whether primary or secondary, and the absence of these structures naturally means an absence of true secretion. There is also usually an associated hypermotility in which the contents seemingly shoot out of the stomach, so rapidly does evacuation proceed.

Just as with the other acidities, we must also study the so called "normal" acidity, that is, the degree which has so often by the multitude been considered anywhere from 40° to 60° for total acid and 20° to 30° for free acid. This degree of acidity, despite the fact that it coincides in degree with the acidity found in the gastric contents of normal persons (noncomplaining), is of little value unless it is considered in conjunction with the quantity of contents, which again brings us back to the degree of secretion and motility. Thus, again, we easily conceive how "dilution," depending upon its degree, correspondingly diminishes the degree of acidity, and how irrational it is to lay stress upon acidity degree solely as such—but even today that mistake is still being made owing to former teachings and misconceptions, and because of the insignificant importance, in the opinion of many, attached to anything else connected with the analysis. Every gastric affection is concerned to a greater or less extent with such disturbances as demand more than an "acidity degree" investigation, and it is for that reason that so much space has been allotted to its consideration in this paper. In the fasting stomach test, we truly have a test for the more grave motor disturbances, but a close study of the test breakfast contents may give us some information relating to the minor degrees of motoric disturbance.

Before we quit the subject of gastric acidity, it is incumbent upon us to pay some attention to the organic acids, since they at times appear in large quantity and by some authorities have been given undue prominence. These acids will be found nearly always in the fasting contents, as might be expected, and should more properly have been discussed in the preceding paper, but as the author had desired to consider the main chemical findings in this paper, so has he proceeded. Ordinarily, these acids are either absent or present in such small quantity as to be of unimportance, in most instances having been introduced with the food. When these acids are present to an appreciable extent, however, we shall almost always find an associated coexisting deficiency of free acid, as well as a defective gastric motility. In the past it had been held that where free hydrochloric acid existed, the formation of organic acids was either retarded or entirely interfered with and vice versa, or in other words, that an incompatibility existed; but of late even these opinions have been scattered. This corrupt relationship may exist to a certain extent, but the formation of these acids may now probably be attributed to a defective or insufficient motility, as a result of which stagnation of food contents occurs in the stomach for periods long enough to cause the production of these acids by fermentation. If this view was not rational, how could we account for the absence of organic acids in that prominent condition known as achylia gastrica? In a simple achylia gastrica we usually have a coexistent hypermotility and rarely a motor insufficiency, yet an entire absence of free acid exists, despite which no organic acids are produced.

We must therefore look for organic acids in cases associated with a certain degree of stasis. In these cases we shall usually find either an absence or a low degree of free hydrochloric acid, while a relatively high degree of total acid exists. The organic acids that may be present are lactic, acetic, butyric, sarcolactic, and the volatile fatty acids, but the one that occurs in greatest amount, when these acids are present, is lactic acid, and for that reason it is chiefly sought in these cases. It may in most instances be taken for granted that when it occurs, some of the other organic acids are also present, though in smaller quantity. The significance attached to lactic acid also practically applies to the other organic acids when present, viz., fermentation as a result of retention of contents for a lengthy period, such as is apt to occur in obstruction of the pyloric outlet, be it benign or malignant. This lactic acid formation is most apt to occur where a subacid state exists. This subacid state probably results from the fact that any acid, if present, has been decidedly diluted by the retained contents, or because a true secretory disturbance (deficiency or absence of acid secretion) exists. In either instance the formation of lactic acid is favored. The depressed secretion of hydrochloric acid or its weakening through dilution will lower its bactericidal action, while stasis, by a prolongation of the fermentation period, gives the lactic acid bacilli, which Miller (4) says always exist in the saliva a better chance to act upon the carbohydrates. Only a few years ago, nearly every case of gastric cancer diagnosed as such before death gave evidence of more or less stagnation of gastric contents, and in these cases lactic acid was nearly always found. For that reason, the presence of lactic acid was considered significant of gastric cancer. This point, although not absolutely reliable, is well worth remembering.

We consider next the significance of the positiveness or negativeness attached to the tests for the ferments, such as the Hammerschlag (5) or Metts (6) methods for the determination of pepsin, and the Boas (7) test for rennin. These tests furnish us with information relating to the degree of

digestive power that the ferments are capable of exhibiting, from which we may infer the extent to which these ferments are present. These tests are usually performed in cases where a low total acidity or absence of free acid exists, because it is in these cases that we often expect to find a diminution of the ferments. The absence of ferment activity points to a very decided reduction or entire failure of the secretion of the ferments and suggests more or less glandular atrophy. It is held by some that a reduction of the one ferment is associated with a corresponding reduction of the other. Others, again, aver that rennet is nearly always reduced to a less degree than pepsin. Boas lays particular stress upon the determination of rennin activity, which is accomplished by a study of the result of the action of different dilutions of gastric contents upon milk. In this test, the rennin of the contents and the calcium salts, which are added separately, by their combined action form an insoluble casein from the caseinogen of the milk. Boas believes that the gastric contents of a healthy stomach, when diluted one to 150, will complete this process of coagulation. A diminution may indicate some pathological state, such as more or less glandular atrophy or some neurotic secretory involvement. A diminished secretion of the ferments, the direct result of a depression of the secretory apparatus, must always be thought of and may occur in such conditions as hysteria, tabes, neurasthenia, and other neurotic affections. When a marked deficiency of rennin activity becomes manifest, however, there is as a rule an indication of either a severe intractable form of gastritis with its resulting atrophy, achylia, or malignancy. When coagulation occurs only up to tubes of one in ten or one in twenty dilution, the cause may be either acid salts or the free acids of the contents, if present, and it does not necessarily mean that rennin must be present. Coagulation in tubes beyond one in twenty and up to one in 160 or over, speaks for the presence of rennin. The contents that show rennin activity at a high degree of dilution contain a correspondingly high quantity of ferments. In states where a marked deficiency or absence of ferments is manifest, we may think of a chronic gastritis of more or less aggravated type, either simple or complicated by cancer or other diseases or consequent to some former constitutional disease; an atrophy of the mucosa the result of some former local disturbance; a neurotic secretory disturbance of local or systemic origin; and a true achylia, probably congenital. This test for rennet is as a rule sufficient for information relative to ferment activity, for when the ferment rennin is markedly deficient in activity, we deduce an even more marked peptic deficiency. By some, a lipolytic action is attributed to a ferment of the stomach (gastric lipase), but its action is considered so slight normally as to not warrant consideration in this paper.

Another test very much performed of late is the so called Wolff-Junghann's (8) test or soluble albumin test for cancer, in which the principle involves the precipitation of the soluble albuminous products of the gastric contents found in increased quantity in gastric cancer. It is stated that the test breakfast contents in gastric cancer contain a very high degree of these albuminous products, much higher than is found normally, and for this reason a great deal of significance is attached thereto. When a dilution of the contents at one in 200 or beyond shows evidence of immediate albuminous precipitation after the Wolff reagent has been added, it is regarded as significant of gastric cancer. Of course, it is understood that the contents in these cases should contain no free acid, in order that the test may be given some reliance. Only recently this test has been declared somewhat irrational, however, so far as its significance is concerned, since it is held that any soluble albuminous material found in the contents may possibly come from numerous sources other than that for which the test is significant. This material may have its origin in the test breakfast, swallowed secretions, blood, secretions from the stomach wall proper, whether involved by disease or not, etc., and for that reason it is believed by some that a high albumin content does not of necessity speak for any gastric malignant lesion. This reasoning is, indeed, very rational and would place in abeyance any tendency we might have offhand to diagnose a cancerous state. Should we be able to rule out the possibility of large quantities of swallowed bronchial or salivary secretions, however, material from sinuses or carious teeth, excessive bleeding, and should we have been certain that the stomach was empty at least six hours before the test breakfast was taken, then this test might have rather definite significance, for it is possible that the stomach in malignancy may secrete a fluid of high albuminous content, either from the growth itself or from some portion of its wall.

Special tests concerned with the products of carbohydrate and protein digestion are made use of when especial demands arise, and may give valuable information, but for ordinary clinical work are seldom thought of.

Occult blood, if found, would have a significance similar to that of bleeding described in the author's preceding paper on the fasting stomach contents.

The gaseous products of digestion, although indicative of fermentative processes involving carbohydrate or albuminous food, even if in abnormal quantity, are not of exceptional importance, since we can through a study of other phases of the case acquire information of similar value.

In this paper the author endeavors to give a generalized view of the significance of gastric findings in as practical a manner as possible, laying particular stress on what he considers most important, but again wishes to state that each case must be studied from every angle before a diagnosis dare be made.

Our Readers' Monthly Prize Discussions

Twenty-Five Dollars Is Awarded for the Most Satisfactory Paper

All persons, whether subscribers or not, are invited to compete for the prize of $25 offered for the reply deemed best by the editors to the following questions:

CLXXI.—How do you treat a sprained ankle? (Closed.)

CLXXII.—What are your methods of resuscitation and aftercare of persons apparently drowned? (Answers due not later than July 15th.)

CLXXIII.—How do you perform circumcision? (Answers due not later than August 15th.)

The award will be based solely on the value of the information contained in the answer. No importance will be attached to literary style. Answers should preferably contain not more than six hundred words, and should be written on one side of the paper only. All papers submitted become the property of the JOURNAL, and should bear the full name and address of the author for publication. The prize will not be awarded to the same person more than once within a year.

The prize of $25 for the best answer to Question CLXX has been awarded to Dr. Henry J. Noerling, of Valatie, N. Y., whose paper appears below.

PRIZE QUESTION CLXX.

THE PREVENTION OF PERINEAL LACERATION.

By HENRY J. NOERLING, M. D.,
Valatie, N. Y.

Prevention of perineal laceration at childbirth should be in the mind of every obstetrician owing to the large number of women who are obliged to submit to repair of the perineum at some time during their lives, and because of the remarkable sense of support given a woman after thorough repair.

Cases where laceration cannot be prevented. Women with naturally small outlets; those with a hard, fibrous perineum, either normally so or as a result of a previous repair; where forceps must be used, particularly at the outlet; where the fetal head is too large; and where there is an abnormal fetus to contend with.

The more common causes are: 1. Indifference on the patient's or the physician's part. The physician is not called in time to assist at the birth, or, if called, is often hurried and leaves the case, returning to find labor over and a perineum torn; other physicians prefer to let nature do all and offer no help at the perineal stage, particularly in bringing the shoulders through. 2. Often the physician is too eager to see a case over quickly and resorts to forceps, perineal stitches being of no moment to him. 3. Leaving forceps on the child too long after their work is accomplished in high forceps operations. 4. Not being familiar with the operation of symphysiotomy.

Prevention. Give obstetrical cases first attention always, remembering that more than one life must be given due regard. Lysol will be found the best antiseptic owing to its lubricating property. See that the rectum is thoroughly emptied and that a full bladder is not going to impede labor. Teach the patient how to use her pains properly, keeping the spine well arched backward into the bed when straining, the knees well flexed and spread apart, thus putting tension upon the symphysis.

Head presentations. When the fetal head is beginning to distend the perineum, give chloroform in small amounts only to relieve the intensity and force of the pains. The index and large finger of the operator are brought into use. The fingers are kept between the oncoming head and the perineum, thus offering a greater dilating force to the vulva. Between pains a side to side massage and stretching of the vulva and vaginal wall of the perineum helps to soften it markedly. The head should be held back until we are satisfied that the vulva, and particularly the perineum, can be gently worked back over the head, with either the fingers or, better, a small ball of cotton dipped in lysol; this is better than to allow the head to force its own way through. Carefully release the posterior shoulder and arm, first, before the next pain jams this shoulder against the perineum and thus causes a tear; bring the anterior shoulder and arm through, and finally, the hips and pelvis slowly.

Breech presentations. The same care should be observed in releasing, first, the posterior and then the anterior leg and hip before the breech presents entirely through the vulva. Give the same attention to the arms and shoulders. Finally massage carefully the perineum over the presenting aftercoming head, holding the fetus as in the usual breech delivery.

Forceps delivery. Never use forceps unless they are indicated. In high forceps operations, remove the blades before the head is brought too forcibly against the perineal body, then proceed as explained above under head presentations. In low forceps deliveries, work only with each pain and with patient only partially anesthetized, at the same time holding the head back till the perineum softens. This will secure a minimum of laceration.

Episiotomy. This is a procedure rarely indicated, although every practitioner should be familiar with it.

The writer submits this article as a result of the study of one hundred private cases in which he tried to minimize the need of perineal stitches. These cases represent eleven primiparæ and eighty-nine multiparæ.

Occiput anterior	77 cases
Occiput posterior	1 case
Breech	5 cases
Breech with forceps	1 case
Forceps (occiput)	10 cases
Craniotomy	1 case
Hydrocephalus	1 case
Eclampsia	1 case
Version	3 cases

The perineum was stitched in only six cases, three primiparæ, two of which were forceps cases, and three multiparæ, each with a repaired perineum from a previous birth. The five last primiparæ presented nothing but a torn fourchette in each case.

Dr. James Harold Howard, of York, Pa., writes:

The practitioner should endeavor to aid the head in passing out of the vagina in the most favorable position, well flexed and with occiput forward, except in the case of face presentation when the chin should be anterior and the head fully extended. The lower bowel should be emptied with a soapsuds enema prior to delivery.

Delivery in the lateral position with the thighs partially flexed affords some advantage over the dorsal position in protecting the perineum, and this is especially so in primiparæ. The perineum is readily observed, weight of the fetal head is relieved, and the uterine and abdominal muscular contractions are counteracted by gravity, as the fundus uteri sinks down on the bed, thus giving the perineum a little longer to dilate.

Strong pressure made against the perineum in my mind predisposes to a tear; however, when the perineum is becoming distended hot compresses of bichloride of mercury gently applied afford great relief and aid in relaxing the tense perineal muscles.

When the head appears at the vulva its descent should be guarded by direct pressure against the presenting part, allowing it to advance a little with each pain, provided that there are no complications demanding a rapid delivery. It should recede in the intervals between pains; if it does not, it is well to push it back so that the next contraction may be partly spent in recovering lost ground. In exceptional cases where the membranes have long been ruptured and the vagina is dry, a vaginal douche of creolin or lysol will facilitate the advance and retreat of the head.

Partial anesthesia is of great value in protecting the perineum, in that we have more control over our patient, the sensitiveness to pain is diminished, and the resulting relaxation of the perineum enables us to enucleate the head as follows: My assistant administers the anesthetic continuously instead of intermittently from one or two pains prior to what would have been the last pain, and at the same time I instruct my patient to breathe deeply and not bear down. Pressure is made on the fundus, if necessary, to prevent the head from receding. As the head advances, gently push the clitoris and labia minora back, allowing the occiput to escape under the pubic arch, relieving some of the tension on the perineum and at the same time assist muscular relaxation with the compresses mentioned above. A sterile pad is placed midway between the coccyx and anus, and moderate pressure is made forward and upward, gently enucleating the head.

In uncomplicated instrumental deliveries when the head is approximately within two tractions of being delivered I remove the blades and enucleate as in a normal delivery. I believe this method has greatly reduced my lacerations in operative cases.

The shoulders may damage the perineum as much as, or even more than the head. Lift the anterior shoulder well up behind the pubes and deliver the posterior shoulder and arm and then the anterior. Very light anesthesia will aid in delivering the shoulders.

Episiotomy, when properly executed, is a prophylactic to severe perineal lacerations in cases where we encounter scar tissue, edema, persistent occiput posterior, elderly primiparæ, lacerations beginning around the anus, and emergencies demanding rapid delivery. It is not justifiable as a routine measure.

I have witnessed severe lacerations from allowing the instruments to slip off the advancing head. It is well to keep one finger in contact with the presenting part as a preventive measure.

Preliminary digital stretching of the perineal muscles may be found beneficial prior to administering pituitrin, in elderly primiparæ and in breech presentation. The injudicious use of pituitrin is to be condemned. Finally do not forget craniotomy in overgrowth or persistent malpositions with a dying or dead baby in preference to severe maternal lacerations.

Dr. Burke Diefendorf, of Hillsdale, N. Y., observes:

Prevention of tears of the perineum in childbirth depends largely on five factors: 1. Elasticity of the perineum; 2, expelling force; 3, time of passage over the pelvic floor and perineum; 4, size of engaging circumference of head and size of shoulders; 5, episiotomy. Bearing in mind that nearly all perineal tears are in the posterior median line, it has been my practice to relieve the strain at that point as much as possible. During the first stage of labor I see that the bladder is emptied, and the rectum thoroughly cleaned out with an enema, thus helping to maintain a normal position. I then examine the perineum to determine the rigidity of the vaginal orifice. If there is much scar tissue, I apply warm antiseptic packs, which are kept on until the perineum begins to bulge. To my mind one of the most frequent causes of tear is too rapid passage of the head over the pelvic floor and perineum.

Especially is this true with the use of pituitrin. My maxim is—*don't hurry* the perineal stage of labor if you would save the perineum; allow at least thirty minutes for delivery after the perineum begins to bulge. I seldom find it necessary to administer chloroform at this time, but control the descent of the head by pressing it up into the subpubic arch. It may be well to add that I always deliver my patients in the dorsal position, as they seem to be able to control the abdominal muscles better and do not bear down as much during the pain in the perineal stage of labor. At the beginning of a pain I insert a finger between the head and the vaginal orifice and allow it to remain until the height of the pain, in this way ascertaining the degree of tension. After the head has been held at the vaginal orifice for at least twenty minutes, which is usually long enough to stretch the perineum sufficiently, I let it slip past just as a pain starts, then holding the anterior shoulder well up against the subpubic arch, I wait until the next pain for delivery of the shoulders.

I have often seen a normal head delivery with no lacerations, only to find an extensive tear after the

birth of the shoulders; and I think a large proportion of physicians could bear me out, if they observed conditions and were honest with themselves. To my mind the posterior shoulder is often overlooked or delivered carelessly. Too often no attention is paid to the birth of the shoulders. After the birth of the head, it is my custom to pass two fingers behind the posterior shoulder and allow it to ride out on them during the next pain, thus preventing the shoulder from ploughing through the perineum, which probably has a mucous tear already and is easy to tear further.

The frequency of tear in breech presentations is largely the result of undue haste; if time is taken and the head kept with its long axis in the proper direction, the number of tears will not greatly exceed the number of tears in head presentations.

It is my practice during forceps delivery to remove the blades as soon as the perineum has been well stretched.

As a last resort, where the tension seems too great and a tear inevitable, I perform a unilateral episiotomy.

(*To be continued.*)

Contemporary Comment

Putting a Grown Man in Charge.—Under this head *The Sun* for June 18, 1916, pays a compliment to an esteemed assistant editor of the NEW YORK MEDICAL JOURNAL, in an editorial article on the recent inspection of the kitchens of New York, hotels, and restaurants.

Dr. Charles F. Bolduan of the health department, remarks the *Sun,* has squelched the enthusiastic young men who amused themselves last week upsetting the stomachs and impairing the appetites of patrons of restaurants and lunch rooms by announcing that of 265 examined, only one was "good," eight "fair," 256 were "bad." The suppression of these bulletins should have been accomplished before their issuance began, but as nothing can be done nowadays without the assistance of brass bands and press agents, the community may count itself fortunate that this foolish and unfair conduct was tolerated for only a week.

The impression conveyed by the announcements of the health department was that the vast majority of the eating houses subjected to its scrutiny were unfit for the purpose they serve, and were under the management of men whose principal desire was to sell dirty and unwholesome food to their customers. This is not the case. The health department score card seems to have been devised expressly to condemn. Apparently only a state of absolute perfection in accordance with the rules of the department could win for a restaurant the rating "good," and to attain "fair" a most unusual degree of compliance with the regulations is required. Nobody with a head on his shoulders believes that of 265 restaurants—any 265 restaurants—in New York, only one would win the approval of reasonable persons on the grounds of cleanliness, quality of supplies and manner of service. Nobody who eats his meals in public places will credit the record that 256 of any 265 restaurants in town are "bad." The thing is preposterous.

Every effort of the health department to improve conditions deserves public support. No man or woman who takes breakfast, luncheon or dinner in a restaurant wants to eat bad or badly prepared food. All of them are enlisted for cleanliness and decency in the preparation of their food, and not a few of them know when these conditions are observed. But the health department appears to have been made the victim of infantile notoriety seekers, and its foolish outgivings have seriously impaired its prestige.

The Care of Drunken Men.—That Cincinnati has made great strides in civic betterment in the past few years is a matter of gratification to all good citizens. There remains to be made one greatly needed reform which should have immediate attention. This concerns the method of handling our delinquents and perpetrators of minor crimes. In dealing with juvenile offenders we have taken a step in advance. After much effort our ancient *bastille*, the House of Refuge, has been abandoned and its children moved to farms. The next place that needs radical changes is our workhouse.

Our present method of dealing with alcoholics is a relic of barbarism and a disgrace to any civilized community, observes E. W. M. in the *Lancet-Clinic* for May 20th. A "drunk" brought into court, sentenced to so many days in the workhouse, stays there long enough to get very thirsty; term expires, is turned out; proceeds to satisfy that thirst; drunk again; back again, to court, to workhouse; out again with same old thirst, and ready to swing the same circle once more. Thus, innumerable dipsomaniacs alternate between sprees and thirsty days in the workhouse. Some have served thirty, forty, and fifty terms. One poor woman has had eighty sentences. There is neither sense, humanity, nor a vestige of science in the whole procedure.

In the first place, the law should allow an habitual drunkard to be sentenced for an indeterminate period; the release to be made on the recommendation of the medical staff. The place of confinement should not be a prison, but an institution for care and treatment. This institution should be a large farm removed from the city, with provision for all kinds of work, so that those committed could be given the work for which each is best fitted. This institution should have a medical staff of trained experts with full charge of the medical treatment, including a prescription for work, its kind, amount, etc. The business of the institution should be under the direction of experienced business managers. Such an institution, once thoroughly equipped and organized, would be self sustaining. The object of the institution should not be punitive but curative. The drunkard or criminal found incurable should be kept permanently in custodial care and given whatever work he is best capable of doing. If he has a family, whatever he earns beyond the cost of keeping him and a small percentage to be applied to the payment of overhead expenses, should be given to his family. How much human wastage could thus be conserved to the great benefit of the community and to the delinquents themselves is self evident.

NEW YORK, SATURDAY, JULY 1, 1916.

THE MEXICAN SITUATION.

The mobilization of the National Guard for service on the Mexican frontier has brought into active military service a large number of medical officers of the guard, who for the first time will be confronted with the grave problems of hygiene involved in the handling of large bodies of men. Fortunately many of the medical officers have already given careful study to these problems, and the higher military authorities have been brought to a full realization of the supreme importance of sanitation in camp life. We can count confidently upon the absence of any such sanitary scandals as that of Chickamauga Park, where during the mobilization of the National Guard for the Spanish war thousands of cases of preventable disease occurred through lack of proper sanitary precautions.

Medical officers of the National Guard will find that life under rigid military discipline is quite different from the practice of medicine in civil life. There will be less room for individuality, there will be constant and sometimes annoying restriction of action and initiative, there will be tedious and almost endless details of organization to be looked after, and all this along rigidly prescribed lines which may prove extremely irksome to men of a certain temperament. On the other hand, medical service in the field offers many interesting problems for study and will give scope to the surgeon for service to his country unexcelled by that of any other branch of the military establishments.

Mobilization has gone on very much more rapidly and more effectively than it did at the outbreak of the war with Spain. We seemed to have learned something, although the delay in entraining the troops which were ordered direct from their armories to the Mexican border, showed that there is still much to acquire in the matter of preparedness. The principal cause of delay seems to have been the faulty system of supplying extra equipment. At present, the respective commands of the National Guard are supplied with sufficient equipment only for the number of men enrolled on a peace basis, which is about fifty per cent. of the war strength. When the command was issued to mobilize the guard and increase it to full war strength, it became necessary to get additional equipment from the depots of the regular army. To ship this to every State in the Union in the right proportion and in the right number necessary involved considerable time. The system should certainly be revised, and each command kept supplied with sufficient equipment in reserve to fit it out at full war strength.

The medical department of the National Guard of the State of New York and possibly of other States as well, has been an exception to the general rule in having been kept up to eighty-five per cent. of its full war strength. In view of the importance of the work of the medical department, and of the difficulty in obtaining trained medical officers the wisdom of this practice becomes apparent. It should be a great comfort to the families of the members of the National Guard of the State of New York to know that in the medical department, at least, there has been a complete state of preparedness.

TESTIMONY WHICH MAY MISLEAD.

Dr. Torald Sollmann, who testified in the suit recently brought by a patent medicine concern against the association journal, made some statements that may both mislead and rejoice some of the irregular practitioners and omniscient laymen who are always on the lookout for good points of attack on the profession. His statement that he had never practised medicine will not absolve him in the minds of the uninstructed. According to the *Journal A. M. A.* for June 17th, page 2007, Doctor Sollmann testi-

fied concerning the modern treatment of pneumonia, in part as follows:

Take pneumonia. Pneumonia is a disease that runs a perfectly definite course. We know that. A patient gets a high fever; gets sometimes out of his head; he gets worse and worse for about four or five days. At the end of that five days a sudden change occurs; he either dies, or he gets well by himself, practically without any treatment. Before people fully realized that—they now know it, most of them, well enough—but before they realized that, they used to be giving all kinds of drugs in the treatment of pneumonia, drugs and other things, baths, and all sorts of things. They would give those, and the patient would go on, and after the five days, a certain number would get well, and a great many people attributed that to this drug, or that, or something else. It has been now shown, had they left those patients strictly alone, they would have gone through exactly the same course of events . . . many infectious diseases are the same way, they run an absolutely definite course, and we know what is going to happen.

All the foregoing testimony, as is perfectly proper, is open to perusal by the laity. Had the remarks been made before an audience composed exclusively of physicians, misunderstanding would have been impossible. All the connotations of Doctor Sollmann's statements would have been thoroughly understood. Physicians comprehend that the attending physician and the nurse would be far from idle during an attack of pneumonia, that symptoms would be treated as they arose, that the heart would be watched, plenty of fresh air would be secured, the skin and bowels would be attended to, the diet carefully prescribed, the sharp pleuritic pain controlled. Perhaps venesection would be performed. The average practitioner would order inhalations of oxygen under certain circumstances; indeed, it would be an unusual case in which no drugs were given, expectorants to lessen the cough, hypnotics for the sleeplessness, even opium, unless it was positively contraindicated. The patient would certainly be treated, if the pneumonia was not.

Such a course is far from what the laity will gather from Doctor Sollmann's evidence to be the latest and most scientific method of handling a patient with pneumonia. It is not at all unlikely that those who read this evidence will conclude that the profession has renounced drug therapeutics altogether, and they may begin to ask why the doctor should call daily or twice daily if he frankly acknowledges that he knows of nothing that will control the crisis. Moreover, what Doctor Sollmann said of pneumonia may soon, in the popular mind, be associated with every acute disease, which would convey a most unfortunate and distorted impression of the facts.

THE EFFECT OF CONSCIOUS SEXUAL INHIBITIONS.

Whatever may be considered the social justification for such artificial sexual inhibitions as are exemplified in coitus interruptus or coitus reservatus, it is certain that these practices have a most deleterious effect upon the systems of the persons who indulge in them. They often betray a desire to obtain overstimulations which perhaps other methods no longer furnish. They add perceptibly to the nervous pressure under which so many already live, and whose systems can little afford the added nervous strain.

While it is the trend of a higher civilization to keep reflex action under as central control as possible, this control refers to a control of function in its entirety and not the component activities of a function, once set in motion. Having set a function in motion, its stoppage has the same effect upon a nervous system as would be the effect on an explosive contrivance of lighting the fuse and stopping up the muzzle. The effect is, sooner or later, to shatter the nervous system.

Whereas the normal sexual function is depletive and sedative in its ultimate result, these practices are entirely congestive and irritative. Continual irritation of the nervous system is evidenced in the numerous types of sexual neurasthenics. Besides, in the case of coitus reservatus, while it is intended thereby to prolong the individual sexual cycle, this purpose is really defeated in the end because the general period of sexual potency is shortened—impotency setting in at a much earlier time. This condition is aided by the irritability and instability of the central nervous system. So far as their nervous effects are concerned these practices are more pernicious than the more condemned practice of masturbation.

Moreover, the undue and prolonged congestion entailed in these practices is the cause of very tangible and depraved physical conditions. They are the most prolific cause of the prostatic enlargements so common in middle life. It is easy to see the mechanism of this condition. The continual congestion causes the formation of connective tissue: often there is set up a nonspecific indolent urethritis. Indeed, such a condition in the male should always arouse a suspicion of one or other of these practices. Indulgence in such practices is due to the general ignorance of their baneful effects, and the enlightenment of the public by the profession should do much to curb it.

KILLING THE COCKROACH.

There is a well worn story of a doctor who was called in the night to take a man from one end of the city to the other, presumably to see a patient, but really because his fee was cheaper for the man he carried than the hire of a cab. Whether this is a true story or not, it is certain that the family physician is asked to do many things, not all of

which are obviously connected with the healing art. Many ways to dispense with what have been called the minor horrors of war have been discussed in the medical journals since the present conflict began, but it is seldom that we find literature bearing on what might be called one of the plagues of peace, Blatta orientalis, in short, as Micawber would say, the cockroach.

Bearing in mind this dearth of material on the subject, we are indebted to Dr. Joseph J. H. Holt, of England, who for two or three years has persecuted the restless roach with all the means which science could suggest; he publishes the casualties in the *Lancet* for June 3d. He has powdered his insect enemy with everything from quinine to mustard, suffocated him with poisonous gases, and boiled him in oil. Altogether this indefatigable doctor has experimented with no less than 124 methods of dealing with the pest and his conclusions are worth recording. The best agents for quick destruction are bromine and sulphur dioxide. These agents must be used at least once a day for two or three weeks before the roaches definitely decide that the immediate atmosphere is unhealthy. As the room should be sealed when the gases are used, the method is impracticable for household use. Creosote, wood naptha, or the oil of rosemary, eucalyptus, or citronella, placed daily near their haunts for several weeks, will effectually rid the place of them, but of course the odor of such an agent is somewhat pungent. A dusting powder naturally suggests itself, and Holt finds that powdered sodium fluoride is the best and cheapest for the purpose.

Apart from its academic interest, these studies become of considerable value when we consider the cockroach as a possible disease carrier and are also alive to the dangerous nature of many of the pastes and other compounds offered to mitigate the pest, preparations which contain such things as arsenic and phosphorus.

IMMUNITY IN TUBERCULOSIS.

A consummation devoutly to be wished is the discovery of some method by means of which the human race may acquire immunity to tuberculosis: such immunity, if obtained, would indeed be one of the greatest advances of medical knowledge. For many centuries there has been a struggle between humanity and the tubercle bacillus, the one trying to acquire a resistance, the other a virulence sufficient to overwhelm its victims. The scales have gone up and down many times, but for some years past the ravages of the bacillus have become distinctly less. For that reason now is a most opportune time to make further attempts to control this affliction, and the attempts must be made along other paths than those of hygiene. Much can be and has been done in that way, but alone it cannot win the struggle. There must be found some method by which the individual can be protected.

Unfortunately tuberculosis appears to be one of those infections that do not confer a high degree of immunity. Although indications of this disease have been found in the bones of Egyptian mummies of 3500 B. C., yet no inherited immunity has developed. We are still fighting for our lives and must so continue. Inasmuch as there seems to be little if any natural immunity, the greatest amount of work has been directed along the line of artificial immunization, but as yet without satisfactory results.

The majority of the infectious fevers can be controlled or modified by the injection of the dead bodies of the invading organisms with their subsequent absorption. In tuberculosis similar attempts have been made, but with little encouragement, as the waxy structure of the bacillus interferes with its absorption.

As a result of the unsuccessful employment of dead bacilli it seems, as Koch remarked, that the only chance lies in the employment of living tubercle bacilli. This is, of course, fraught with more or less danger, but it is in this direction that the advance must be made.

It is evident, however, that the older people become the less likely they are to be infected with tuberculosis. It is also well known that the great majority of people have been infected at some time by tuberculosis, but have overcome the infection; it seems, therefore, that an infection may produce an immunity of some degree.

As it is in childhood that the greatest susceptibility exists, so during that age our greatest efforts must be exerted. If we can vaccinate successfully, or, in other words, increase, even to a slight degree, immunity in childhood, there will be less infection then and fewer cases in later life.

CONGENITAL CYANOSIS OF SYPHILITIC ORIGIN.

M. E. Jeanselme (*Presse médicale*, December 2, 1915) presented to the Société médicale des hôpitaux on November 26, 1915, an eleven year old girl in whom had tardily appeared all the physical and functional signs of cyanosis. An interesting point was that the physician had been observing in the girl's mother the evolution of a case of syphilis from the date of infection and had established the fact that this "blue child" had been conceived and carried by the mother while the latter was suffering

from secondaries. Several times Jeanselme had treated the girl for lesions unmistakably specific, circumanal syphilides, for example, and perionychia.

One of the brothers of the little patient, six years of age, suffered from an abortive form of cyanosis; he had the indentations of the shins characteristic of inherited syphilis. The Wassermann test was positive in both these children. Another brother, seven and a half years old, was not cyanotic; he had a regular course of mercurial inunctions beginning shortly after birth. He has no syphilitic stigmata, although the Wassermann test is positive in him also. The youngest of the family, a boy of four years, seems alone to have escaped all traces of syphilis.

THE ABSORPTION OF A USEFUL JOURNAL.

Dr. Charles Chassaignac and Dr. Isadore Dyer, managing editors of the *American Journal of Tropical Diseases and Preventive Medicine,* announce in the June issue of that periodical its absorption into the *New Orleans Medical and Surgical Journal.* The former managing editors bespeak the interest of all members of the Society of Tropical Medicine as well as of those who have helped by subscriptions to the defunct journal, and hope that the additional material afforded by the combination will be found more than compensating. In closing the affairs of this *Journal,* they desire to express the utmost appreciation to all who helped along the way, and to assure everyone that in the new arrangement the interests of all will be considered and conserved. The excellent and venerable New Orleans organ will gain by the change, and the subscribers, who are thoroughly protected, will be pleased.

News Items

Yale University to Open Medical School to Women.—Announcement is made that at a recent meeting of the Yale Corporation it was voted to approve the recommendation of the executive board of the school of medicine, that a limited number of women be admitted to the Yale Medical School.

Medical Women's National. Association.—This organization of women physicians, which was formed in Chicago last November at the golden jubilee of the Mary Thompson Hospital, held its first annual meeting in Detroit, on Tuesday, June 13th. Dr. Eliza Mosher, of Brooklyn, honorary president of the association, presided at the opening session of the meeting.

The Medical Society of New Jersey.—At the 150th annual meeting of this society, held in Asbury Park, June 20th, 21st, and 22d, Dr. Philip Marvel, of Atlantic City, was elected president, succeeding Dr. William J. Chandler, of South Orange. Other officers were elected as follows: Dr. William G. Schauffler, of Lakewood, first vice-president; Dr. Thomas W. Harvey, of Orange, second vice-president; Dr. Gordon K. Dickinson, of Jersey City, third vice-president; Dr. Thomas N. Gray, of East Orange, reelected recording secretary; Dr. Harry A. Stout, of Wenonah, reelected corresponding secretary; Dr. Archibald Mercer, of Newark, reelected treasurer.

Infantile Paralysis in New York.—According to figures compiled by the health department, twelve deaths from infantile paralysis were reported during the week ending June 24, 1916. Of these, eleven occurred in Brooklyn. The health department also reports that on June 26th thirty-seven new cases of the disease were reported, making a total to date of 183 cases in Brooklyn.

Hospital Supplies for the New York National Guard.—A gift of $25,000 to the New York National Guard has been made by Mrs. Cornelius Vanderbilt, to be used for hospital supplies as may be needed. Announcement of the gift was made by Lieutenant Colonel William S. Terriberry, chief surgeon of the New York Division, who has been commissioned to spend the money to the best advantage.

Assistants Wanted.—There is opportunity for two assistants in the Department for Diseases of Digestion and Metabolism at the German Polyclinic, Second Avenue and Eighth Street. Those who have had some chemical training are preferred. The hours are Tuesday, Thursday, and Saturday, from 2 to 4 p. m. Apply to Dr. A. I. Ringer, German Polyclinic, Second Avenue and Ninth Street.

Doctor Zinke Honored.—Dr. E. Gustav Zinke has resigned as professor of obstetrics in the Medical College of the University of Cincinnati, after serving for twenty years in that capacity. A dinner was tendered to him on the evening of June 19th by the medical profession of Cincinnati in recognition of his services. Dr. C. L. Bonifield acted as toastmaster and presented Doctor Zinke with a silver loving cup. Among those who spoke were Dr. C. R. Holmes, Dr. C. W. Dabney, Dr. William Gillespie, and Dr. Hugo O. Pantzer, of Indianapolis. Doctor Zinke spoke on My Country and My Profession and My Love for Both.

Navy Medical Corps Examinations.—The next examination of candidates for appointment in the Medical Corps of the United States Navy will be held on or about August 7th at Washington, D. C., New York, Boston, Philadelphia, Norfolk, Va., Charleston, S. C., Great Lakes (Chicago), Ill., Mare Island, Cal., and Puget Sound, Wash. Applicants must be citizens of the United States and must submit satisfactory evidence of preliminary education and medical training. Full information regarding the physical and professional examinations, with instructions how to submit a formal application, may be obtained by addressing the Surgeon General of the Navy, Washington, D. C.

Street Accidents in New York.—During the year ending May 1, 1916, there were 2,120 accidents in which persons were killed or injured in Greater New York, according to the current issues of the *Police Bulletin.* These figures show an increase of seventy-nine over the previous year, in which 2,041 accidents were reported. In Manhattan alone 1,221 accidents occurred. Brooklyn had the next greatest number—612; the Bronx, 185; Queens, 87, and Richmond, 15. The largest number of accidents occuring in any one section were reported from the First District, which includes the territory between Fourteenth Street and the Battery and embraces the most thickly populated portion of the city.

Personal.—Alonzo Milton Nodine, D. D. S., assistant dental radiographer to the New York Nose, Throat, and Lung Hospital, and oral surgeon and dental consultant to the French Hospital, New York, has been appointed dental surgeon to the French Hospital of New York Military Foundation at Passy, France.

Dr. A. Strachstein, of New York, has been appointed chief of clinic and clinical instructor to the department of urology, Cornell University Medical College.

Dr. Frederic H. Gerrish, of Portland, Me., has resigned as professor of medical ethics at Bowdoin College. Doctor Gerrish was a member of the faculty of this institution for forty-four years.

Professor Selskar M. Gunn, director of the division of hygiene of the Massachusetts State Department of Health, has tendered his resignation, to take effect August 31, 1916. Dr. Lyman A. Jones, of North Adams, has been appointed his successor.

The Death Rate in New York.—During the week ending June 24, 1916, there were reported to the Department of Health of the City of New York 1,311 deaths from all causes, compared with 1,277 during the corresponding period in 1915, the respective rates being 12.24 and 12.22 in a thousand of population. The death rate for the first twenty-six weeks of 1916 was 14.82, compared with a rate of 15.10 for the first half of 1915.

Generous Bequests to Philadelphia Institutions.—The following bequests to Philadelphia institutions are included in the will of Charles W. Kolb, who died in Philadelphia on May 28th, leaving $1,000,000 to charity: Samaritan Hospital, $100,000; Temple University, $100,000; Christ Home for Homeless and Destitute Children, $100,000; Presbyterian Board of Foreign Missions, $200,000; Presbyterian Board of Home Missions, $200,000; Presbyterian Orphanage, $100,000; Presbyterian Home for Aged Couples and Aged Men, $100,000; Children's Country Week Association, $100,000.

Medical Unit Sails for Service with Central Powers of Europe.—Six doctors and six nurses, composing the sixth medical relief expedition to be sent from the United States to the Central Powers under the auspices of the American Physicians' Expedition Committee, sailed last Saturday for Rotterdam on the Holland-American liner *Ryndam*. The party was headed by Dr. Joseph Rilus Eastman, of Indianapolis, Ind., professor of surgery in the University of Indiana. The other physicians were Dr. H. Oberembt, of Milwaukee; Dr. Hubert Dunn, of Kentucky; Dr. Herrmann Schumm, of Sauk City, Wis.; Dr. Ralph Bettmann, of Chicago; and Dr. C. Rueth, of Milwaukee.

Civil Service Examinations.—Among the positions for which the Civil Service Commission of the State of New York will hold examinations on Saturday, July 15th, are the following: Assistant bacteriologist, Quarantine Laboratory, Department of the Health Officer of the Port of New York, men and women. Salary, $1,200 per annum. Physician, State prisons and reformatories. Salary, $2,000 without maintenance. Examination open only to men who are licensed medical practitioners in this State. Assistant physician, State prisons and reformatories. Salary, $1,500 without maintenance. Examination open only to men who are licensed medical practitioners in this State. Assistant physician, regular or homeopathic. This examination is intended to provide eligibles for the position of assistant physician in the State hospitals and for other positions of a similar nature in various State and county institutions. Salary in the State hospitals, $1,200, increasing $100 each year to $1,600, with maintenance.

Jefferson Medical College Commencement.—The degree of doctor of medicine was conferred upon 162 graduates at the ninety-first annual commencement of Jefferson Medical College, Philadelphia, held on Saturday, June 3d. This is said to be the largest graduating class in the history of the institution. The address was delivered by Dr. W. W. Keen, his subject being The Doctor's Duty. The award of two graduate degrees and of twenty-two prizes for college work were other features of the commencement exercises. Thirty-four States and Porto Rico, Nova Scotia, England, Persia, and Syria were represented among the graduates.

The American Posture League will hold a joint meeting with the American School Hygiene Association, Wednesday, July 5th, at 9:30 a. m., in the auditorium of the Horace Mann School, Teachers' College, New York. The program will include the following papers: The Relation of Posture to Health, by Dr. Eliza M. Mosher, of Brooklyn; Good Posture as a Condition of Efficient Brain Activity, by William H. Burnham, Ph. D., professor of pedagogy and school hygiene, Clark University; The Work of the American Posture League on School Furniture, by Dr. Henry Ling Taylor, of New York; Eye Strain and Posture, by Dr. E. M. Alger, of New York; The Relation of Clothing to Posture, by Dr. L. E. La Fetra, of New York; An X Ray Study of the Effects of Exercise, Posture, and Dress on the Position of Internal Organs, by Dr. Nathalie K. Mankell, of Buffalo, N. Y.; The Importance of Intensive Work on School Hygiene, by Lewis M. Terman, Ph. D., professor of education, Leland Stanford Junior University. Miss Jessie H. Bancroft, assistant director of physical training in the public schools of New York, will demonstrate, class room methods for training correct posture.

Fourth of July Preparedness.—In 1903, 415 persons in the United States acquired lockjaw (tetanus) following Fourth of July pistol and firecracker wounds. In 1908, there were 76 such cases with 55 deaths, and last year there were only 4 cases of lockjaw with 3 deaths. Two factors have led to this gratifying decrease in this unnecessary loss of life, namely safe and sane celebrations of Independence Day, and the prompt use of tetanus antitoxin. The antitoxin, while almost infallible as a preventive of lockjaw, has little value after the disease is fully developed. Inasmuch as the disease so often follows Fourth of July pistol and firecracker wounds, it is of the utmost importance to have tetanus antitoxin injected promptly. The department of health has for some years supplied tetanus antitoxin free of charge, and on request will even send a trained physician to inject the remedy. Not a single case of lockjaw has occurred in any patient promptly injected.

War Plans of the American Red Cross.—Colonel Jefferson R. Kean, Medical Corps, United States Army, who is director general of military relief for the American Red Cross Society, announces that the society has undertaken the organization of base hospital units from the personnel of the larger civil hospitals of the country. These base hospitals, each of which is equipped to receive 500 patients, are intended to be transported on the outbreak of war to the seat of military operations. Although organized by the Red Cross, they are not administered by it, but when called into active service pass under the exclusive authority of the War Department. The medical officers receive military commissions in the reserve corps, and volunteer commissions when called into active service. The nurses in the same way belong to the Red Cross Nursing Service, and in time of war become a part of the Army Nurse Corps.

The organization in time of peace of these units will place at the disposal of the government immediately on the outbreak of war organizations which it would require many weeks to create and equip, and offers our soldiers from the first the finest medical talent in the country. The following are the locations of these hospitals and the heads of their various services:

Presbyterian Hospital, New York.—Director and chief of surgical service, Dr. George E. Brewer; principal assistant, Dr. Alfred Stillman; chief of medical service, Dr. Warfield T. Longcope; chief of laboratory service, Dr. Karl M. Vogel; chief nurse, Miss Anna C. Maxwell.

Mount Sinai Hospital, New York.—Director, Dr. N. E. Brill; chief of surgical service, Dr. Howard Lilienthal; chief of medical service, Dr. R. Weil; chief of laboratory service, Dr. George Baehr; chief nurse, Miss Elizabeth A. Greener.

Bellevue Hospital, New York.—Director and chief of surgical service, Dr. George David Stewart; chief of medical service, Dr. Van Horne Norrie; chief of laboratory service, Dr. Charles Norris; chief nurse, Miss Clara D. Noyes.

New York Hospital, New York.—Director and chief of surgical service, Dr. Charles L. Gibson; chief of medical service, Dr. Lewis A. Conner; chief of laboratory service, Dr. William J. Elser; chief nurse, Miss M. H. Jordan.

New York Post-Graduate Hospital, New York.—Director, Dr. Samuel Lloyd; chief of surgical service, Dr. Edward W. Peterson; chief of medical service, Dr. Arthur F. Chace; chief of laboratory service, Dr. Ward J. MacNeal; chief nurse, Miss Amy Patmore.

Brooklyn, N. Y., for Navy.—Director and chief of surgical service, Dr. W. B. Brinsmade; chief of medical service, Dr. Luther F. Warren; chief of laboratory service, Dr. Robert F. Barber; chief nurse, Miss Frances van Ingen.

Massachusetts General Hospital, Boston.—Director, Dr. Frederic A. Washburn; chief of surgical service, Dr. George W. W. Brewster; chief of medical service, Dr. Richard C. Cabot; chief of laboratory service, Dr. J. Homer Wright; chief nurse, Miss Sara E Parsons.

Boston City Hospital, Boston.—Director, Dr. J. J. Dowling; chief of surgical service, Dr. Edward H. Nichols; chief of medical service, Dr. John Jenks Thomas; chief of laboratory service, Dr. Arial W. George; chief nurse, Miss Emma M. Nichols.

Harvard University, Mass.—Director and chief of surgical service, Dr. Harvey Cushing; chief of medical service, Dr. Roger Lee; chief of laboratory service, Dr. Richard P. Strong; chief nurse, Miss Carrie M. Hall.

Lakeside Hospital, Cleveland.—Director, Dr. George W. Crile; chief of surgical service, Dr. W. E. Lower; chief of medical service, Dr. C. F. Hoover; chief of laboratory service, Dr. H. T. Karsner; chief nurse, Miss Grace Allison.

Rochester, N. Y.—Director, Dr. John M. Swan; chief of surgical service, Dr. C. W. Hennington; chief of medical service, Dr. William V. Ewers; chief of laboratory service, Dr. C. C. Sutter; chief nurse, Miss Emma Jones; assistant, Miss Jessica Heal.

Johns Hopkins Hospital, Baltimore.—Director, Dr. Winford Smith; chief of surgical service, Dr. I. M. T. Finney; chief of medical service, Dr. T. C. Janeway; chief of laboratory service, Dr. T. R. Boggs; chief nurse, Miss Bessie E. Baker.

Harper Hospital, Detroit.—Director, Dr. Angus McLean; chief of surgical service, Dr. C. D. Brooks; chief of medical service, Dr. B. R. Shurly; chief of laboratory service, Dr. P. M. Hickey; chief nurse, Miss Emily McLaughlin.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Twenty-sixth Communication.

ETHER AND CHLOROFORM.

The frequency with which these two anesthetics are used make a résumé of their physiological action desirable, especially for the general practitioner.

On the central nervous system these vapors produce a progressive downward paralysis, the action of chloroform being the more rapid. The medulla is the most resistant portion of the whole system, and the motor synapses throughout are less promptly affected than the sensory and receptive. It is assumed that ether and chloroform act through a solvent action on the fatty constituents of nerve cells.

The most important immediate action, after that producing unconsciousness, consists of the effect produced on the circulatory system. On the heart these vapors produce a progressive weakening of the auricles, with a toxic dilatation of the ventricles —a weak, slow heart action resulting. This effect is much more marked with chloroform than with ether; with chloroform the toxic action may be so sharp and severe as to quickly paralyze the heart, while ether may have relatively little effect on the heart until very late in the third stage of anesthetization. The exact mechanism of this depression of the heart is not satisfactorily explained, acute irritation of the inhibitors alone not seeming adequate.

With ether there is a preliminary rise in blood pressure, followed by a slow, steady fall; whereas with chloroform there is a continuous, though not necessarily rapid fall from the beginning, and this is more marked throughout than the fall produced by ether. In either case the fall of blood pressure is believed to be due to irritation of the vasodilators, resulting in a varying vascular relaxation. With ether the relaxation is more pronounced in the peripheral area, while with chloroform the principal seat of action is the splanchnic area; hence, in part, the facial pallor of chloroform anesthesia of the third stage, contrasted with the flushing seen when ether is administered.

With ether vapor the respiration is temporarily slowed from reflex irritation of both the trigeminal and the vagus, ether being the more irritant at first; but the slow, shallow breathing of the third stage is due to direct depressive action on the medulla.

In giving ether or chloroform it is customary to watch the pupil pass through a primary dilatation into a secondary contraction, at which point it is desirable to hold the extent of anesthesia, since a secondary dilatation with continued administration is usually indicative of impending coma. Contraction is assumedly due to irritation of the third cranial nerve: coma dilatation, to paralysis.

In the general metabolism chloroform tends to induce fatty infiltration, especially of the liver, degeneration being unfortunately a not infrequent sequel. Ether tends to form pulmonic complications, chiefly through a lowering of vital resistance, due in part to depressant action on the epithelium and in part to the high latency of heat in ether vaporization.

Absorption of ether or chloroform is exceedingly rapid through the alveoli of the lungs; excretion is largely by the same route, and is very prolonged, especially with ether, the characteristic odor of which is detectable on the breath of the patient from twelve to twenty-four hours after an operation, especially if the period of anesthetization has been unusually prolonged.

Both of these vapors are dangerous, hence they should be administered by those only who understand the reactions produced, and who are keenly alive to the responsibilities of the situation. Chloroform is estimated to be three times as depressant as ether and eight times as toxic.

Luargol or 102 in Syphilis.—G. Milian, in *Paris médical* for May 6, 1916, refers to a compound of dioxydiaminoarsenobenzol with bromine, silver, and antimony recently elaborated by Danysz. Experiments in the trypanosomiasis of rabbits showed that this compound will regularly yield a cure at a stage of the disease in which other arsenicals, including atoxyl, arsenophenylglycin, and arsenobenzol, frequently fail; in the last stage of the disease luargol will cure five out of six rabbits where the other compounds, in equal doses, have no effect whatever. The compound differs from arsenobenzol in that it gives better results when injected in small, repeated doses than in one large dose. It is supplied as an orange yellow powder, insoluble in water, but very soluble in caustic soda, with which it forms a dark brown solution. Luargol in the dose of 0.1 gram dissolves in 1.1 c. c. or better 1.5 c. c. of normal soda solution, and the injection is made with this solution diluted to one per cent. in sterile distilled water. As with salvarsan, the patient should fast before the injection and remain quiet for a few hours after it has been given. In the treatment of syphilis Danysz counsels injections in progressive doses of 0.15, 0.2, 0.25, and 0.3 gram, up to a total of 1.2 to 1.5 gram; intervals of two, three, or four days should be allowed between injections. Febrile and general reactions following injections of luargol are much less marked than after salvarsan. A patient who could only withstand 0.45 gram doses of neosalvarsan, augmentation beyond this point being impracticable owing to the chills, headache, and vomiting which followed even these amounts, received increasing doses of luargol, up to 0.3 gram amounts, without febrile reaction or other disturbance. Two cases of slight arsenical erythema have been observed after luargol, but no "nitritoid" attacks. The drug has pronounced therapeutic

activity, syphilitic manifestations disappearing at times even more rapidly than after salvarsan or neosalvarsan. It has shown itself active in cases in which salvarsan failed to overcome ulcerative secondary lesions of syphilis. The new compound appears, therefore, to be an improvement over previous means of treatment in this disease.

Antianaphylactic Precautions in the Serum Treatment of Tetanus.—Genouville, at a recent meeting of the surgeons of the Fifth French Army (*Presse médicale,* May 8, 1916), reported five cases —additional to others previously reported—in which, with antianaphylactic precautions, injections of tetanus antitoxin were given to wounded men who had previously received such injections after former wounds. A preliminary injection of one c. c. of antitoxin was made very slowly into a vein at the bend of the elbow and a few minutes later a subcutaneous injection of ten c. c. administered. Of the five patients one acquired a mild serum eruption, another a temporary rise in temperature, and a third, suffering from bronchitis at the time, paroxysmal cough and faintness lasting fifteen minutes after the preliminary intravenous injection. In this last patient the subcutaneous injection was given on the next day without the least untoward result. These cases are held to demonstrate that, provided the antianaphylactic precautions referred to are taken, antitetanic prophylaxis can be applied without danger in wounded men who have received an injection of antitoxin some months before.

Rational Emetine Therapy.—R. L. Levy and L. G. Rowntree, in the *Archives of Internal Medicine* for March, 1916, point out, as a result of clinical observations and numerous experiments in animals, that the administration of emetine hydrochloride is not to be regarded as a harmless procedure, ill effects sometimes following its use, even in therapeutic doses. A man suffering from amebic dysentery and lues received twenty-nine grains of emetine subcutaneously in a period of twenty days. After slight amelioration this treatment was followed by violent diarrhea, abdominal pain, increasing albuminuria, acute renal insufficiency, acidosis, bronchopneumonia, vasomotor collapse, and death. A woman with pyorrhœa alveolaris, who received four half grain injections on successive days, acquired a distressing diarrhea lasting six days, with pain in the back and abdomen and tenesmus, these symptoms then gradually subsiding. The experiments and clinical notes of the authors showed that the toxicity of the various commercial preparations of emetine varies widely, and likewise that patients differ markedly in their susceptibility to the drug. Individualization in emetine treatment is therefore essential. The drug should preferably be given subcutaneously and in courses at intervals of several days or a week. In amebic infections Levy and Rowntree consider one third grain three times a day for a week or ten days usually a safe dose. It is rarely necessary to administer more than one and a half grain daily. According to Bass and Johns, one half grain of emetine daily for from three to six days is all that is required in pyorrhea. It should be borne in mind that over a long period of time even relatively small doses of emetine may prove harmful. Intravenous injections of emetine should be given only in extreme cases. Small doses, well diluted, e. g., one half grain in 100 c. c. of salt solution, should alone be used. The injection should be made slowly, and the blood pressure meantime be carefully observed, the experiments of the authors having shown that a sudden, pronounced drop in pressure is readily induced by this drug when given intravenously. The oral route of administering emetine is impracticable, even small doses causing marked irritation.

Intestinal Obstruction in Children.—T. Jason Wood (*British Journal of Children's Diseases,* June, 1916) remarks that apart from intussusception these cases are rare. Two cases are recorded, in one of which the first symptoms were associated with the respiratory organs, cough, etc., but there had been no bowel movement for two days. The temperature was 103° F., the abdomen was considerably distended and slightly tender all over with no local swelling. The rectal examination was negative. The following morning it was possible to make out a tumor in the region of the umbilicus, cylindrical in shape, resembling intussusception, and operation was advised. The following day the operation was performed. There was a mass, apparently tuberculous in nature, infiltrating three or four inches of the small intestine and its mesentery. It was fixed and could not be delivered through the wound. A lateral anastomosis was done and the child made a rapid recovery. The second case presented a cyst of the mesentery about the size of a duck's egg in the lower part of the ileum. In this case there had been no bowel movement for five days and she had vomited every day, the vomitus being fecal in character. At operation a gangrenous bowel was found and was resected.

Varied Aspects of Military Surgery.—R. Le Fort (*Presse médicale* for May 4, 1916) after observations in the Balkan wars in 1912, felt certain of the advantages, in nearly all cases, of prudent over bold surgery and of aseptic over antiseptic methods. Experience at the battle of the Marne in 1914 completely dispelled such impressions, the frequency of tetanus, gas gangrene, suppuration, etc., soon showing that painting of a wound with tincture of iodine and applying an individual dressing constituted a hopelessly inefficient method. Later improvements in transportation of the wounded and in the dressing of the wounded at the first aid posts, together with the institution of good base hospitals, restored to vogue academic discussions on the relative value of antisepsis and asepsis, but at any moment present views may again be upset. On the whole, it is clear that the surgical indications vary from one period, place, or series of wounded men to another. The present elative frequency of shell and shrapnel wounds and the short range at which bullet wounds are often inflicted greatly aggravate the average clinical course of the wounds met at present. The nature of the cases, and hence surgical indications, also vary, whether observations are made in an ambulance, a field hospital, or a base hospital.

and according to the type of military operations being conducted at the time. Thus, in large battles with continuous movement of entire armies, the medical corps is unavoidably overloaded with an immense number of cases requiring attention, and under shifting and unfavorable conditions, whereas in trench warfare, conditions are far better and surgical indications approximate those of civil practice. Other variable factors exerting a marked influence on military surgical practice are the physical and mental state of the troops at the time, the race to which the wounded men belong —Serbians and Bulgarians, as well as Moroccans and Senegalese, resisting infection better than the French and Germans—and the skill of the surgeons applying the initial treatment to the wounds. The good military surgeon must be a specialist in surgery and know how to adapt his treatment to the varied conditions under which the wounds are received and given care.

Trench Foot Tetanus.—George G. Davis and Joseph J. Hilton (*Journal A. M. A.*, June 17, 1916) report the case of a rifleman who had been in the trenches five days exposed to the cold and wet. On admission to the hospital both feet were reddened and edematous, the edema extending to slightly above the ankles. The great toe on the right foot was slightly blackened and all the toes were more or less cyanotic. Anesthesia was present over the entire surface of the foot. After a week in the hospital stiffening of the muscles of the jaw developed and 2,000 units of tetanus antitoxin were given. Later the muscles of respiration were involved and the patient died ten days after admission. The patient had had no prophylactic dose of tetanus antitoxin. All cases of trench feet should be considered as wounded and a prophylactic dose of antitetanic serum should be given.

Phagedenic Gangrene Following Vaccination.—F. Balzer and E. Moulard in *Bulletin de l'Académie de médecine* for May 2, 1916, state that the complications of vaccination, relatively rare, present varied clinical aspects, including vaccinal ulceration, erysipelas, lymphangitis, vaccinoid furuncle, abscess and phlegmonous inflammation. Phagedenic tendencies in these complicating lesions have at times been noted, and have been overcome successfully by Brocq, by means of a five to ten per cent. collargol ointment, hot air, and the thermocautery. In the case reported by the authors, a healthy adult of fifty-one years, acquired after vaccination a phagedenic ulcerative gangrene of the arm, ultimately invading the anterior aspect of the thorax down to the second rib, and the entire back and nuchal region. Cauterization and the use of various antiseptics during a period of seven months, including the employment of phenyl salicylate, methylene blue, and hot air, failed to stay the gangrenous process. A solution of trioxymethylene in glycerin removed the offensive odor. Finally, by the use of two polyvalent serums, that of Leclainche and Vallée and later that of Wurtz, prepared with organisms obtained from the wound, suppuration was arrested, extension of the disease checked, and the projecting gangrenous margins obliterated. The patient, nevertheless, succumbed from cachexia. In this case the infecting pyogenic organisms were of many varieties, Bacillus pyocyaneus, according to Wurtz, probably playing the principal role. Neither to the technic of vaccination nor the vaccine used is the gangrenous complication ascribed, 300 other persons having been vaccinated under like conditions on the same day without any untoward result. Poor resisting power and insufficiency of antibodies, together with secondary infection of the vaccination wound by scratching or rubbing by the clothing, are held to account for the serious complication witnessed. The patient was far from home and living under unhygienic conditions at the time.

Treatment of Gunshot Wounds by Packing with Salt Sacks.—Alfred J. Hull (*Lancet*, May 27, 1916) describes this method which has as its object drainage of cavities by the osmotic action of salt. Sacks are made of bandage and gauze sewed into shape, filled with salt and sterilized in an autoclave. When introduced into wounds the free end is immersed in saline solution and drainage takes place by capillary attraction. The salt remains undissolved for several days and forms a concentrated solution promoting resolution of inflammatory induration and aiding the separation of dead tissue by dissolving coagulated lymph. Six days is the average time that the sacks remain in the wound, thus obviating frequent dressing.

Psoriasis of Traumatic Origin and Its Treatment.—Gaucher and Klein, in *Paris médical* for May 6, 1916, refer to numerous cases of psoriasis starting more or less suddenly after a nervous shock or wound which they have met since the beginning of the European war. In a woman of twenty-five years, a refugee from Arras, psoriasis over the occiput was first noticed on the day after the bombardment of that town, and later extended to the back and lower extremities. In soldiers, psoriasis often developed over the scars of healed wounds. The treatment consisted in thorough removal of the scales and the application of the following ointment, which yielded excellent results and was nearly always well borne:

℞ Sulphuris præcipitati, }
Camphoræ pulveris, . } .....āā 1 gram;
Acidi salicylici, ... }
Olei cadini, ...10 grams;
Zinci oxidi, ...20 grams;
Petrolati albi, ...30 grams.
Fiat unguentum.

The patients received a thorough bathing with soap every other day. Complete cure or marked betterment always followed the above mentioned treatment.

Duodenal Tube in Gallbladder Disease.—Max Einhorn (*Journal A. M. A.*, June 17, 1916) states that if turbid bile is found in the duodenum in the fasting condition, cholecystitis with gallstones is usually encountered. Turbid bile may be present without gallbladder disease in cirrhosis or neoplasms of the liver or in structure of the duodenum below the ampulla of Vater. Clear bile may exceptionally be associated with biliary calculi; in

this case the gallbladder is not inflamed, or the gallbladder is entirely filled with calculi. The diagnosis of cholecystitis or cholelithiasis cannot be made from the appearance of the bile alone; with other clinical signs it is of great assistance. In the treatment of gallbladder lesions a weak solution of ichthyol or argyrol was instilled into the duodenum just above the ampulla of Vater. The plan of treatment is based on the idea that an astringent effect on the duodenum and the papilla of Vater will exert a beneficial effect on the bile duct. The treatment is given in the fasting condition. Cases of catarrhal jaundice and minor affections of the gallbladder not requiring surgical interference were much benefited by this method of treatment.

Quinine and Urea Hydrochloride as a Local Anesthetic in Tonsillectomy.—The advantages of this solution, according to Louis J. Burns (*Annals of Otology, Rhinology and Laryngology,* December, 1915) are that it is absolutely nontoxic even in as strong a solution as ten per cent. It always produces sufficient anesthesia to complete the operation without the necessity of stopping to make further application or injection. There is marked diminution of afterpain and discomfort. It has advantages over cocaine and its derivatives, owing to its nonsystemic action. There is absence of troublesome primary or secondary hemorrhage. It may be readily sterilized, frequently recurring high temperature producing no chemical or physiological change.

Treatment of Head Injuries.—Alexander Don (*Lancet,* May 20, 1916), in writing of cases treated in casualty clearing stations at the front in France, states that in two to four hours unconscious patients recovered sufficiently from shock to allow of operation. Scalp wounds are excised and trephining done when necessary—shell wounds almost always produce cerebral abscess. Indications for operations are the presence of a penetrating wound of the head, the fitness of the patient to take a general anesthetic and experience of the surgeon in cranial surgery. Cleansing of the scalp wound, opening of the cranium to allow the escape of blood and brain debris and restoring pulsation give good immediate results. Superficial drainage is preferable to the deep method.

The Nauheim Method.—Simon Baruch (*Medical Record,* June 17, 1916) describes the true Nauheim method which is often misunderstood and misused. The rationale may be divided into two essential elements; the effect of the carbon dioxide and that of the salines. The hyperemia of the skin seen in a carbon dioxide bath seems to be due to a specific mechanicochemical irritation by the bath. There is also a heightening of cutaneous sensibility with an enhancement of respiratory activity from absorption of carbon dioxide by the skin. There is no doubt of the superiority in therapeutic effect of natural carbonic acid water over the artificially prepared in cardiac disease. The principal guide to a prescription of the Nauheim method whether natural or artificial is adaptation of the bath in duration, temperature, and gas and mineral contents to each case and a careful watching of the response of the heart to the bath. Omitting the salines is as unwise as omitting any element of asepsis in surgery. In imitating the Nauheim bath the water temperature should not be higher than 94° F. nor lower than 86° F. unless the patient reacts well and is improving.

Treatment of Chronic Cough (*Journal of the Med. Soc. of N. J.,* May, 1916):

℞ Terpini hydratis, ...3i;
Alcoholis, ...3i;
Syrupi pruni virginianæ, ...3iii.
M. et Sig.: Teaspoonful, three or four times a day.

Treatment of Nervous Cough (*Journal of the Med. Soc. of N. J.,* May, 1916):

℞ Codeinæ, ...gr. v;
Acidi hydrocyanici diluti, ...3i;
Elixiris aurantii, q. s. ad.....3iv.
M. et Sig.: Teaspoonful, four or five times a day.

Serum Treatment of Typhus Fever.—Charles Nicolle and Ludovic Blaizot, at a recent meeting of the Académie des sciences, Paris (*Presse médicale,* April 13, 1916), reported that they had found it practicable to produce an immunity to typhus fever in horses and donkeys by repeated inoculations of emulsions of spleen or adrenals from guineapigs suffering from typhus infection. The serum thus obtained, tried first in animals, was found to possess distinct preventive as well as curative properties. It is nontoxic to man, and was used in nineteen patients with typhus fever, with favorable results.

Congestion in the Treatment of Cerebrospinal Meningitis.—Duncan Forbes and Eveline Cohen (*Lancet,* May 27th, 1916) advocate the production of cerebral congestion in these cases by raising the foot of the bed so that the patient's body is at angle of 14° to 23° with the floor, while no pillow is allowed. In mild cases this results in a few days in normal temperature and free movement of the head with uninterrupted recovery. In severe cases the temperature rises and recovery is more gradual. Too high raising of the foot of the bed causes severe headache and persistent vomiting and requires a lowering of the bed with relief of tension by spinal puncture. The method was first tried in cases which showed low cerebrospinal pressure and threatened to become chronic, but it has also shown good results in the early stages of the disease. The patient should lie on the back as much as possible without pillows.

Fainting Attacks in Children.—Robert Hutchison (*British Journal of Children's Diseases,* June, 1916) reports that these attacks last from a few minutes to three quarters of an hour. The patients usually are very pale, but do not become wholly unconscious. Girls are more frequently affected than boys. The attacks do not come on, as a rule, until after the age of five years. The cause may be overstrain at school. The condition is to be diagnosed from minor epilepsy; in the latter the seizure is not as long and consciousness is usually gone. It is probable that the attacks are pimarily nervous in origin and due to a temporary sympathetic paralysis leading to uncontrolled action of the autonomic system with vasodilatation in the splanchnic area and inhibition of the heart. Removal from

school, change of air to the seaside, strychnine and attention to the digestive organs usually bring about a speedy disappearance of the attacks.

Treatment of Hepatic Failure in Malaria and Yellow Fever.—Andrew Balfour (*Lancet*, May 20, 1916) agrees with Hunter that such cases require a keeping up of the supply of both protein and sugar. Glucose is administered by mouth or enema in solutions of five to ten per cent., while protein is given in peptonized enemata of beef tea, eggs, etc.

Treatment of Phlebitis in Typhoid.—Santa Maria y Marron (*Revista de Medicina y Cirugia Practicas*, May 14, 1916) reports a severe case of bilateral phlebitis of the leg in typhoid where brilliant results followed the use of enemata containing ten grams of pure peptone with 100 grams of fresh liver pulp emulsified therewith. Liver extract was also given by mouth. Pain disappeared in six days as did shortly afterward all physical signs.

Ozonized Isotonic Sea Water in the Treatment of Wounds.—R. Guyot and C. M. Rogues, at a recent meeting of the Société de biologie, Paris (*Presse médicale*, April 13, 1916), report favorable results from the use of sterile isotonic sea water for dressing wounds. Isotonicity with the body fluids is obtained by diluting the sea water with pure water sterilized in the autoclave. Further sterilization is procured by means of ozone, of which 8.7 grams are used in the treatment of every cubic metre of water. According to the clinical observations made, the resulting ozonized water exerts a marked effect in accelerating tissue healing.

The Antiseptic Properties of Iodized Oil.—In a communication to *Roussky Vratch*, for February 20, 1916, V. Golovin tells of his experience with iodine in oil as an antiseptic and antipruritic application in cases of wounds, boils, eczema and ulcers. He employs either olive or cottonseed oil to which a few drops of the tincture of iodine are added, the amount of iodine depending on the strength desired. The oil is heated in an open vessel and the iodine added drop by drop, stirring after each addition with a glass rod. It is put into a stoppered bottle. When freshly prepared the oil has the color of iodine, losing the color on standing. It is the decolorized oil that should be used. The author obtained satisfactory results with this preparation.

Treatment of Flat Foot in Soldiers.—Robert Jones (*British Medical Journal*, May 20. 1916) divides the treatment into three stages. In the first acutely tender stage the patient is kept in bed and gentle massage used. In the second stage the foot is adducted and inverted and kept continuously so if necessary, using plaster of Paris for ten days. The third stage, after the removal of the plaster, calls for massage and exercise, avoiding movements or eversion. Boots are then fitted to the feet with straight inner border of the sole, long heel raised on the inner side, and a patch is put on the inner side of the sole still further to invert the foot. Cases due to peroneal sprain call for exsection of the tendons. Contrast baths of hot and cold water may be used to stimulate the circulation, while electricity is of service in hastening the recovery.

Therapeutic Value of Spleen Extract.—H. M. Harrower (*Medical Record*, June 3, 1916) advocates the use of spleen organotherapy in anemia, malnutrition, leucopenia, malaria, typhoid, and tuberculosis. Its action is the production of leucocytosis.

Röntgenographic Control of Pneumothorax Treatment in Pulmonary Tuberculosis.—I. Seth Hirsh (*Medical Record*, June 10, 1916) states that x ray control assists in selection of cases, permits estimation of the degree of collapse of the lung and the effect on the opposite lung, it allows the study of the progress of the disease, it indicates graphically the displacement of the heart and mediastinum, and it makes possible the early discovery of complications. Both the plate and the fluoroscopic methods should be used.

Anaphylaxis in the Treatment of Gonorrheal Complications.—Louis D. Smith, in *Journal A. M. A.*, June 3, 1916, finds that patients who are markedly affected by anaphylaxis respond to the treatment with the specific serum. Factors other than the antibacterial play an important part, as when normal horse serum is substituted for antigonococcic serum the results are the same. To what factor the beneficial results of treatment with horse serum are to be attributed cannot be definitely stated. The best results are obtained at the time of the onset of serum sickness and the greater the reaction the better the result.

Laminectomy with Simple Exposure of the Spinal Cord.—Charles A. Elsberg and Pearce Bailey in the *Journal A. M. A.* for June 10, 1916, state that the free removal of spinous processes and laminæ with opening of the dura, in the absence of increased intradural pressure or a discoverable lesion, may be followed by a disappearance of normal cutaneous and tendon reflexes for a number of hours, or perhaps by the temporary return of pathological reflexes. The operation of laminectomy may have a profound effect in certain pathological states of the spinal cord and may so modify or check the disease that a return to normal conditions is possible. Because of the safety of laminectomy in experienced hands, except in the region of the conus and the cauda equina, exploratory operations should be done more frequently.

Epifascial Method of Injection of Mercury and Salvarsan Derivations.—A. L. Wolbarst (*Medical Record*, June 3, 1916) states that this method was first used in 1914 by Wechselmann in Berlin, and Wolbarst from personal experience considers it better than the intramuscular method because it provides ready absorption without necrosis, infiltration, or inflammation. The rationale of the method depends upon the theory that medicated fluid injection in proximity to the layers of the fascia lata will cause less pain than when deposited intramuscularly The needle is plunged into the gluteal muscle and then withdrawn, until the point turns freely from side to side. A local anesthetic solution may be first injected which will flow freely back through the needle after the syringe is detached from it when the proper level is reached, and this serves the second purpose of making painless the injection proper.

Miscellany from Home and Foreign Journals

Gas Gangrene.—E. Sacquépée in *Presse médicale* for May 4, 1916, holds that the term gas gangrene is ambiguous and misleading, for at times in true gas gangrene both gangrene and gas are clinically imperceptible, while at others gaseous and gangrenous infections occur which have nothing to do with gas gangrene. With rare exceptions, cases of true gas gangrene present a complex bacterial flora in the tissues involved. Experimental inoculations in animals furnish a basis for determining what bacterial species are the true etiological factors. Sacquépée divides the cases into three groups, that of the edematous forms, that of gas septicemia, and that of diffuse gangrene, the first occurring with relative frequency in the spring and early summer and the second in the summer and fall, while the third prevails at all seasons. The edematous forms are discussed in particular in the present article, and are divided into the pure edematous and the edematogaseous varieties. The former appears usually three to five days after the wound has been received. The limb affected becomes rapidly edematous, and the segment in which the wound lies may double in size in less than twelve hours. No trace of gaseous infiltration is noted, though a characteristic odor gradually appears. The general condition rapidly becomes bad, and death nearly always follows promptly. The initial gangrenous focus is usually found of the size of a large walnut, up to that of the fist. The organism responsible for this as well as the edematogaseous variety is the bacillus of malignant gaseous edema or *Bacillus bellonensis,* a strictly anaerobic bacillus three to ten microns long, often curved, sometimes occurring in chains, but generally separately. Both this organism and its soluble toxin produce edema, with or without gas formation, and cause early death when injected into guineapigs.

The Transmission of Typhus Fever.—The role of body lice in the transmission of typhus fever seems well established by experimental as well as by clinical investigations. Following the demonstration by Nicolle during the epidemic of typhus fever in Tunis in 1906, a number of investigators confirmed the result obtained by him not only by infecting lice with the blood of typhus patients, but by transmitting the disease to monkeys and guineapigs through the agency of the infected lice. Moreover, Nicolle and Conseil transmitted typhus fever to two healthy persons by permitting them to be bitten by infected lice. Thus, from the first demonstration of the relation of the tick to Texas fever, made by Theobold Smith in 1893, to the last evidence that the body louse is concerned in the transmission of typhus fever furnished by Nicolle thirteen years later, wonderful strides have been made in establishing the role of insects in carrying disease from the sick to the well. We may well be proud of the fact that the most notable contributions to this important phase of epidemiology were made by American investigators, Theobold Smith and the Yellow Fever Commission. However, in the case of typhus fever, the evidence that the louse is the sole carrier of the disease is not altogether conclusive. V. K. Stephansky (*Roussky Vratch,* February 20, 1916) has observed a number of cases of infection with typhus fever in which the agency of lice could be excluded with reasonable certainty, as in the case of physicians, students and nurses who never came in such contact with the patients as to become contaminated with the vermin. During an epidemic of typhus fever in Odessa, he observed that the majority of patients came from the better class of inhabitants, while in the cases of relapsing fever, a disease carried exclusively by the body louse, almost all patients were of the lower classes, coming from cheap lodging houses. The author suggests drop infection from the nasopharynx as another possible mode of transmission, pointing out that in the majority of cases of typhus fever, the secretions of the upper respiratory passages are streaked with blood which contains the typhus virus. In sneezing, coughing, or talking, a spray of infected secretions may be projected onto the mucous membranes of exposed persons. It would seem that while lice do carry typhus fever, the possibility of transmission of the disease through secretions containing blood should be borne in mind and guarded against.

Observations on Disorders Due to Meckel's Diverticulum.—Attention is drawn by E. Kirmisson in *Bulletin de l'Académie de médecine,* April 25, 1916, to the possibility of confounding intestinal obstruction due to constriction by Meckel's diverticulum with acute appendicitis. The diverticulum being attached to the bowel only a short distance from the ileocecal valve, symptoms referable to the right iliac fossa often attend the obstructive condition. Diverticular obstruction causes pain and vomiting similar to those of appendicitis, which, in turn, is sometimes complicated by indications of intestinal obstruction. In the case of a boy of fourteen years recently admitted to a hospital for supposed appendicitis, a matted mass of intestinal loops was found constricted by a large adherent Meckel's diverticulum near the brim of the pelvis. The diverticulum was of the same calibre as the small intestine to which it was attached twenty cm. above the ileocecal angle and also by a vascular band containing an artery and two veins at a point a few cm. above, thus forming a noose in which a loop of ileum was loosely caught. The band was cut between ligatures, but the diverticulum was not removed, owing to the patient's poor general condition, until about two months later, when he returned with recurrent obstructive symptoms. Recovery followed. Kirmisson recommends this two stage operation in patients similarly weakened at the time of the first intervention. In the formerly troublesome cases of Meckel's diverticulum open at the umbilicus, forming a fecal fistula, the author first ligates the pouting margins of the canal to prevent outflow of feces, next incises around the umbilicus through the peri-

toneum, delivers the diverticulum and loop of intestine to which it is attached, ligates the diverticulum at its base, removes it with the thermocautery, buries the stump, and closes the abdomen. Three cases were thus treated successfully. Infants operated in for this condition should be breastfed, to improve their resistance to the surgical procedure.

Agglutination Test in Pertussis.—A strongly agglutinating pertussis serum was obtained by O. R. Povitzky and E. Worth (*Archives of Internal Medicine,* February, 1916), by inoculating rabbits intraperitoneally, ten or twelve times at seven day intervals, with living pertussis cultures. By agglutination tests, B. pertussis could be specifically identified from hemoglobinophilic bacilli, pertussislike bacilli, and B. bronchisepticus. In the clinical diagnosis of pertussis, agglutination tests were found to compare favorably with complement fixation only in the first week of the whoop. A dilution of not less than one in 200 was found necessary for a practically positive diagnosis of pertussis by the agglutination reaction.

Diplococcic Pleuropulmonary Congestions.—These affections are now regarded by Umberto Baccarini in *Riforma medica,* May 8, 1916, from clinical observations and laboratory experiments, as systemic, with localization in the respiratory apparatus. Fränkel's pneumococcus first causes a diplococcus septicemia and later becomes localized in the lung—a frank pneumonia. Diplococcemia does not necessarily cause pneumonia, but may cause cerebrospinal meningitis. Varied degrees of severity of pneumococcus infections were shown by Banti to be due not to the patient's powers of resistance, but to a variety of pneumococci with distinct biological characteristics. Pleuropulmonary congestion may be looked upon as the equivalent of an attenuated pneumococcemia, or, as Baccarani terms it, a "modernized pneumonia."

Epidemic Catarrhal Jaundice.—John A. Procter and Gordon Ward (*British Journal of Children's Diseases,* June, 1916) report a patient, a boy aged twelve years, who had enjoyed good health up to the time of the attack of jaundice. For six months he had had repeated attacks of epistaxis, and for three weeks swelling of the feet and abdomen. At the first examination the spleen was found to be enlarged; the liver, however, was normal in size. Diarrhea was present, but no albuminuria. He was seen by another physician in consultation, who diagnosed sarcoma and advised an exploratory laparotomy. As his condition improved, this was not done. Later he became worse, the spleen again being enlarged, bleeding of the gums and edema also being present. Some time later he became acutely ill, was unconscious, with marked retraction of the head and seemed on the point of death. Two days later the head retraction and jaundice had disappeared. He now became very dyspneic, jaundice developed rapidly, and he died in two days. The autopsy showed a hobnail liver and an enlarged spleen; a completely collapsed left lung in a cavity full of recent lymph and exudation. The case had been diagnosed at various times as splenic anemia, tuberculous peritonitis and meningitis, and meningococcal meningitis. Sarcoma, sporadic acholuric jaundice *sine* jaundice and portal thrombosis were also suggested. The blood picture showed considerable anisocytosis and polychromasia, except in one examination.

Myelogenous Leucemia with Hematomyelia.—Romolo Rummo reports in *Riforma medica,* May 15, 1916, a case with fatal termination in a woman of thirty-four years with a syphilitic history, who showed marked splenomegaly, bone tenderness, ecchymoses of the thighs, and whose blood showed an enormous increase in leucocytes. Paraplegia developed in this case with lessened reflexes, neuralgic pains in the legs, and later incontinence of urine and feces. Post mortem examination showed the coexistence of a syringomyelia.

Fecal Concretions of the Appendix.—John Douglas and Leon Theodore LeWald (*Journal A. M. A.,* June 17, 1916) state that a fecalith in the appendix as a rule is not to be seen with the x ray. If calcium salts are deposited on the surface as the result of inflammation it may become demonstrable. A fecalith in the appendix may be mistaken for a ureteral calculus. The passage of an opaque ureteral catheter will usually help in making the differential diagnosis. When the shadow is above the crests of the iliac bones a lateral stereoscopic röntgenographic examination should be made with an opaque catheter in the ureter on the suspected side. If there is still doubt, a Röntgen examination, combined with an opaque meal or an enema, should be made. Finally, in making a differential diagnosis it must be remembered that there are cases in which the appendix is situated on the right side.

Malaria in Flanders.—In spite of the conditions strongly favoring outbreaks of malaria among the troops at the front in Flanders, e. g., purposeful inundation of the plains with brackish water, the resulting formation of stagnant pools, the admixture of already infected colonial troops, and the prolonged occupation of trenches partly filled with water, no epidemics of malaria have occurred, owing to the efficient sanitary precautions taken. F. Rathery and R. Michel, in *Paris médical,* April 22, 1916, have met with twenty-eight cases of malaria with positive blood findings, many of them in colonial men already infected, but some in Frenchmen not previously exposed. In addition, there were twenty-nine cases with intermittent febrile paroxysms but negative blood findings. Among the cases were instances of the ordinary periodic chills and fever (with double quotidian paroxysms in one case), of continued fever with typhoid state, of pernicious malarial fever with typhoid state, and of larval malaria. In some instances malarial manifestations appeared in the course of typhoid or paratyphoid fever. In two cases of paratyphoid B fever sudden febrile paroxysms were noted during the course of the disease and malarial plasmodia were thereafter found in the blood. On the whole, the malarial conditions met were seldom serious, and all seemed to yield to quinine, though sometimes tardily. Administration of quinine by mouth proved insufficient, necessitating

recourse to injections of the drug, which were always well borne. Quinine medication should not be abandoned because it has failed to benefit in twenty-four hours.

An Unusual Stomach Case.—George E. Brown (*Journal A. M. A.*, June 17, 1916) reports that the x ray showed a pouch of the stomach on the lesser curvature near the pylorus. The diagnosis was in doubt, but the most likely was that of gastric ulcer. At operation a hernialike weakening of the stomach wall was found at the lesser curvature near the pylorus. It was plicated with three linen sutures. The recovery was uneventful. There was considerable improvement in the patient's symptoms, but an indiscretion in diet or an excess of alcohol would bring on many of the original symptoms.

Causes of Eczema.—Predisposing causes given by Eusebio de Oyarzabal, in *Revista de Medicina y Cirugia Practicas*, May 7, 1916, are the exudative diathesis of Czerny, with which is related the status thymolymphaticus, also arthritism, gout, diabetes, and disturbances of nutrition, such as overfeeding and excessive adipose tissue. Age is of importance, the newborn furnishing a majority of all cases. Neuroses and neuropathies may produce eczemas. Determining causes are variable, and two factors must be considered, namely, special sensibility of the skin and mucous membranes, and an excitant which acts either internally or externally. Overfeeding is not only a predisposing, but also a recognized determining cause, although proof that it is not invariably so, is seen in the fact that not all eczemas yield to diet, and that as a rule external medication is much more efficacious than regulation of diet. Physical causes are compression, abrasions, lack of fat in the skin, temperature conditions, secretions and excretions, and action of light. Unna is a believer in the parasitic nature of the disease.

Phlebitis migrans.—Carl A. Hedblom, in *Journal A. M. A.*, June 3, 1916, reports the case of a woman in her fourth pregnancy in five years. The labor was uneventful. On the eleventh day the patient had a drenching night sweat with a sharp rise of temperature to 104° F. There was marked tenderness and some induration over the course of the right saphenous vein and the leg soon became swollen and edematous. The usual treatment of rest and elevation, the use of the ice bag locally, etc., was carried out and there was a rather prompt improvement in the temperature and pulse, but the tenderness and swelling extended progressively down to the foot. At the end of the fourth week the temperature rose again to 104° and there was marked tenderness, induration and swelling of the right thigh. This was followed by similar attacks in the left thigh, left side of the neck, axilla, arm and left chest. In all there were six attacks. In the last attack eye and mental symptoms presented and both feet became gangrenous. There was complete recovery. In the course of the illness an autogenous vaccine was made from a blood culture which revealed a nonmotile spore forming bacillus which did not correspond to Bacillus subtilis in its cultural characteristics. Goat serum was also prepared and injected subcutaneously without effect.

Amebic Dysentery in a Man Who Had Never Left England.—Amebic dysentery in the British Isles, as described by C. Worster Drought and D. D. Rosewarne (*British Medical Journal*, May 25, 1916), is extremely rare and this justifies the reporting of a case occurring in a soldier, aged thirty-nine years, who had always lived near Manchester. Then Entamœba histolytica was formed in the stools and the case responded promptly to the emetine treatment.

Duodenal Ulcer Mistaken for Chronic Appendicitis.—Richard Lewisohn (*Medical Record*, June 17, 1916) reports four cases of duodenal ulcer which had been erroneously operated in for appendicitis. Three of the four cases had positive histories and x ray findings with negative chemical analysis, while the fourth had the whole triad, pointing toward duodenal ulcer. The fact that three cases of this type were admitted to one hospital in one day proves that this diagnostic error must occur frequently.

Angioma of the Larynx.—Emil Mayer (*Medical Record*, June 17, 1916) regards angioma of the larynx as rare. In the case recorded malignancy was suspected and an attempt at removal of a specimen for diagnosis might have been fatal. The patient was a woman of fifty-two years who had been hoarse for a year and had had a profuse hemorrhage from the mouth. There was cough and dyspnea on exertion, but no pain. A diagnosis of cancer had been made previously, but careful examination showed an angiomatous growth for which laryngotomy and excision of the mass was done under local anesthesia. The most interesting point in the case lay in the diagnosis, because fatal hemorrhage might have followed the removal of any part by the endolaryngeal method. A review of the literature by Phillips and Ruh showed only twenty-seven cases of this condition.

Indictment of the Tonsil.—Ben C. Gile, in *Annals of Otology, Rhinology, and Laryngology*, for December, 1915, states that in addition to the obstruction to respiration, deglutition, and phonation caused by hypertrophy and other abnormal conditions, the tonsils play an important part in the introduction and dissemination of pathogenic germs. They share in the causation of many morbid conditions which destroy health and endanger life at a time when no local symptoms are manifested. A focus of infection may exist in the crypts, while the surface may show nothing to excite suspicion. In fact, there may be not only a lack of symptoms, but also of notable change in appearance, so that a casual inspection may lead to a negative diagnosis. The tonsils cannot be placed in the class of organs that are presumably healthy until proved morbid. Their structure and location are such as to make them peculiarly liable to invasion. A marked increase of blood pressure during an attack of tonsillitis should cause a thorough investigation of the condition of the kidneys. Cases of nephritis have disappeared after the removal of diseased tonsils. Rheumatism, nervous disorders and many other diseases may be traced to morbid tonsils as the causative factor.

Proceedings of Societies

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held January 17, 1916, at the Academy of Medicine.

The President, Dr. THOMAS S. SOUTHWORTH, in the Chair.

Cancer of the Breast.—Dr. JOHN EDWARD JENNINGS, of Brooklyn, New York, read this paper, which was published in the JOURNAL for May 20, 1916.

Dr. ROBERT T. MORRIS said that the frozen section could not always be depended upon, but nevertheless it was well to make use of it, for two or three reasons. In the first place, if the growth was small the patient might be told that it was of an uncertain nature, but that if she waited for operation until it could be definitely determined it might be too late. If a frozen section was made she might be able to escape with a small operation if the growth was benign. In that way they appealed to the psychology of the patient, aroused her curiosity, and she would be much more apt to consent to prompt operation than allow the growth to go until it became malignant. Women had almost as much curiosity as doctors, and if they could get hold of them early and arouse their curiosity, they could be led up to a frozen section and prompt operation. Otherwise the patient might delay and go from one person to another for advice. She might seek aid from a Christian scientist or from some quack who would massage the growth and hasten its development.

Last year he had operated on the wife of a physician, and had the report from the frozen section that it was a benign growth. Accordingly, the breast only was removed, and the patient came back in six months with a malignant carcinoma. In that case the report was absolutely misleading. In most instances, however, they could determine the condition pretty well. In regard to the question of multiple local recurrence, when the skin area, so well described by Doctor Jennings, had not been removed, the speaker had not been in the habit of removing it, but without reference to his case histories, he could recall very clearly that many did have this local skin recurrence, but when recurrent skin nodules did occur, they were remarkably amenable to the Coolidge x ray or to the gamma rays of radium.

In regard to the division of the minor pectoral muscle, he was at work in Hamburg when Heidenhain made his first study of the deposits of growths in the muscles, and he determined at that time that the minor pectoral muscle was not involved until very late; that had been confirmed by subsequent investigations. Instead of dividing the minor pectoral muscle near its arm attachment, he preferred to use Ruth's device, which consisted of dividing it from its rib attachment, then turning it into the axilla so that scar contraction in the axilla did not count. He depended a great deal on the value of this little procedure, of which he would be deprived if he was to follow Doctor Jennings' plan in that respect.

The point of moving the arm freely after the operation was not sufficiently emphasized by the authorities. He could not recall having heard any one speak of it as Doctor Jennings had done, and yet it was a most important point, for the reason that the joint being supplied in part by the circumflex nerve filled with some degree of exudate on account of the irritation of the circumflex nerve, and this exudate organized and formed adhesions. Many persons after amputation of the breast had a stiff arm and would complain of pain for months or years afterward. A number of such cases had come to him in consultation with the report of scar contraction causing pain, and he had called attention to joint adhesions instead. It was easy to break up the adhesions, and the next week a patient who had perhaps had a stiff arm for several years was ready to turn flapjacks with it.

He regretted that Doctor Jennings had omitted one point on which there was a great deal of discussion, viz., the value of the x rays and the gamma rays of radium in advanced cases. His own experience had been varied in that respect, for he had had cases of recurrence of carcinoma which went right on under the influence of the x rays and the gamma rays as though nothing had been done; others had been kept in check so that the patient gained a year or two years of time, until there were multiple occurrences elsewhere; while in the best group, a smaller group, the recurrent carcinomas had been so well held in check that they were spoken of as cured, temporarily though it might prove to be, but some of the cases had extended as long as seven or eight years (and they were held originally to be hopeless cases). These had been properly treated with x rays and radium. He had no doubt that in these cases conditions were still persisting which allowed the malignant disease to develop in the first place. There might be a tendency for the normal cells to assume an abnormal type of development; the chromosomes then might lead to neoplastic growth. On the other hand, the gamma rays or the x rays might so whip up the normal cells that they would no longer produce an irregular chromosome in new cells. This was the way perhaps in which the x ray and gamma radium acted, not by causing destruction, but by whipping up normal cells so that they no longer produced aberrant cells. This part of the subject was so great that he could only state his belief that they had been too skeptical of the influence of the x rays and radium, for the reason that they had not always been careful to refer patients to the men who used these resources in the best way. He himself had been very fortunate, for he had some patients who believed their cases to be hopeless who now called themselves cured. Only the day before he had seen the wife of a prominent man, a very lovely woman, who had not allowed any one to see her carcinoma until it was very far advanced. Her husband finally discovered it and insisted upon immediate operation. He had operated a year ago and the deposit about the vessels in the axilla was so extensive that the operation could not be completed without amputating the arm, so a mass was left attached to the bloodvessels, which could be easily felt after the closure of the wound. She was then referred to an authority in New York who

uses the x ray and radium extensively. At the present time there was not a sign of cancer in that woman's axilla. She had red cheeks, carried on her social engagements, and had been traveling freely. That was an instance of the remarkable effects of radium, properly used, in a condition about which the profession was too skeptical.

Dr. Edward Wallace Lee said that the way in which the paper was presented left little for any one to add, and its conclusions were of great value. Before hearing the paper he had thought that if Doctor Jennings presented some phases of the subject it would give opportunity for a few questions, though perhaps they might not come strictly under the heading of the paper, i. e., something about the etiology of cancer. There was no disease, not even tuberculosis, which was so agitating the minds, not only of the profession but of the public, and every imaginable form of treatment was being tried. He had come in late, and did not hear whether Doctor Jennings had said anything about the etiology of cancer, though he had heard him say something about abscesses, and he did not know whether the doctor held that the disease was due to some form of irritation. For his own part, he knew of no other cause than irritation in the production of a cancer. His own definition of cancer was an abnormal distribution or an abnormal placement of normal tissue cells. Cancer was perfectly natural when there was a certain irritation of the cells placed in the condition that they were found in cancer. There was nothing unnatural about cancer. It came about as a natural result of certain conditions. It was a natural sequence of cause and effect.

Then as to metastasis—whether or not it traveled through what Sims used to call the absorbents (whatever he meant by that, for he said that it affected the adjacent glands), whether it affected the glandular system primarily, or the blood system primarily. The speaker had always considered it as traveling through the blood system primarily. So far as the surgical technic was concerned, no method had ever been devised that some expert surgeon had not criticised, and perhaps offered one of his own as a method of preference. He had been much interested in what Doctor Morris had said about the efficacy of radium and x rays in certain cases that he had observed; he himself had not been so fortunate.

Dr. J. H. Branth said that some five years ago he had heard Dr. George H. Balleray, of Paterson, N. J., read a remarkable paper before the association, and he recalled some of the remarks he had made in discussing the paper. In January, 1904, he (Doctor Branth) had read a paper stating that he had used x rays extensively in treating cancer of the breast and had not attained a single complete cure. This same statement was repeated in discussing Doctor Balleray's paper. At best, it only held the disease in check. Now, he would have to recall this opinion, for he has seen some cases—though not many—cured by the use of x rays aided by the high frequency high tension current. The x ray treatment, however, must be skillfully applied. If small doses were given they would only make the cancer grow faster. The quantity (dose) that the patient required in order to subdue the cancer was different in different cases. There were not the same conditions in every patient. The doctor must feel his way and give the treatment accordingly. X rays in small doses acted as an irritant and caused the cancer to grow faster. If that view was well founded, irritation would be one cause for developing cancer. Then, again, the large doses recommended by some practitioners had brought the x ray treatment into discredit, owing to the danger of burns. For treatment, the static machine was to be preferred, because the danger of burning was less than by using the coil as a generator.

Dr. J. A. Rivière and Dr. De Keating Hart, both of Paris (which two gentlemen had had a dispute regarding the priority in the use of the high frequency spark and were at war with each other) maintained that they had cured many cases—a result which Doctor Branth had not been able to achieve. Moreover, the treatment was so painful that patients would not stand it except under anesthesia. The high frequency spark had also been used by Czerni, at Heidelberg, but had been abandoned there. The high frequency high tension current was not painful.

It was now generally accepted that cancer in the beginning was a local affection. Why not cut it out quickly? for if left in, it became malignant nearly every time. Why not cut it out before that occurred? The cutting off of a small part for microscopical investigation invited the danger of diffusion through the cut lymph channels. It would show more wisdom to make microscopic examinations *after* removal of the tumor. Whenever a tumor appeared in the breast it ought to be removed by the knife, the excision extending well beyond the borders of the growth. If not originally malignant, it would almost certainly become so in time. In all cancer operations, x rays and high frequency currents should be applied before and after operation, with a view to subdue and kill all cancer cells that might have escaped the knife.

Another theory had been evolved and was described and demonstrated before the association by Doctor De Kraft, that is, that the cancer cells would be killed by high temperature, say 104° F., which temperature normal cells would tolerate. Doctor Nagelschmidt, of Berlin, also had invented a high frequency apparatus whereby he caused the internal tissues to be subjected to similar high temperature. Doctor Branth had used such an apparatus, but found it dangerous, and it had yet to be demonstrated to him that it worked well. He had been trying to get Dr. Francis C. Carter Wood, of the Crocker Cancer Research Laboratory, to come to some meeting of the association and describe some experiments that were being made in relation to the infectiousness of cancer. If the officers of the association could induce him to read a paper on this subject, it might throw some light upon conditions not generally known.

Doctor Jennings had nothing to add, except to thank the gentlemen who had participated in the discussion. He had said nothing about the treatment of cancer by x rays and radium, as his own experience with these agents had not been sufficient

to enable him to give an opinion. It had been his custom in all cases in which he operated, either primarily or secondarily, to send the patient to the x ray man for a vigorous and prolonged course of treatment. He had a few recurrent cases which had remained well, but he hesitated to call them cures. The patients thought they were cured, and perhaps they were.

Doctor SOUTHWORTH said that good team work was not limited to intercollegiate athletics. It was an essential of modern warfare, but had its place also in the arts and times of peace. To be efficacious it must be intelligently aggressive, efficient, and direct its attention to the overcoming of obstacles. Such team work was accomplished in recent years by the members of the United States Public Health Service in the Philippine Islands, and when the history of this work was fully written still further honor would be accorded to the men who within a short time accomplished such marvelous results in those islands. It was a great pleasure to introduce one of the men who took part in these accomplishments, Dr. Victor G. Heiser, director of public health in the Philippine Islands and now connected with the Rockefeller Foundation, who would speak of the recent developments in the treatment of leprosy and give reports of a number of cures, together with some account of his work for the lepers during his administration, and how their segregation had been accomplished.

Recent Developments in the Treatment of Leprosy.—This paper, by Dr. VICTOR G. HEISER, appeared in the JOURNAL for February 12, 1916, page 289.

Dr. GEORGE HENRY FOX congratulated Doctor Heiser upon the excellent work he had done in the study of leprosy and on the success he had achieved in its treatment. His own experience with leprosy during the past forty-five years agreed with much that had been said. Years ago, when he saw more cases of leprosy than at present and had the opportunity to visit a number of large leper hospitals in Norway, Havana, and Trinidad, not to mention New Orleans and San Francisco, he formed certain definite conclusions regarding this disease, some of which had been strengthened by what he had just heard.

His first conclusion was that leprosy was not, as was generally imagined, an incurable disease. In the Canadian leper settlement at Tracadie he once saw an old woman whose fingers had been ulcerated and lost, leaving clublike stumps. This woman was ever eighty years of age, and had had leprosy for forty years, but looked as though she were doomed to die of old age and not of leprosy. Before that he had heard and thought that tubercular leprosy was almost always fatal in seven to nine years. This led him to believe that leprosy, like syphilis, in certain robust individuals might tend to run its course and leave the patient clinically in perfect health, with no external manifestations of active disease.

Another conclusion was that chaulmoogra oil was the best remedy, if not the only one, which had any decided effect on the progress of the disease. Some twenty-five or thirty years ago he had written upon the advantages of chaulmoogra oil in leprosy and reported a case apparently cured. The patient was a man from the Sandwich Islands, who was treated in his hospital service with chaulmoogra oil. In a short time the manifestations of leprosy had nearly disappeared. Later he went to California, where he met his wife and children and settled upon a ranch. He had reported at intervals, asserting a steady improvement, and after nine or ten years he wrote that he was still perfectly well and had no symptoms except the deformity of his fingers, which might be regarded as the result rather than as an evidence of the disease. After that the speaker lost track of the man, and could not say what had become of him. In all the cases in which he gave chaulmoogra oil, a rapid and decidedly beneficial effect was produced.

Another opinion which he had formed was that arsenic, strychnine, and similar remedies had absolutely no effect upon the progress of the disease. Most of the cases which he treated with chaulmoogra oil received alternating treatment with nux vomica when the digestion became impaired by the oil, but he never felt that nux vomica, however beneficial as a tonic, had any effect upon the course of the disease. It was easy to see that the hypodermic administration of chaulmoogra oil might be better than its internal administration, and also that the camphorated oil might be a valuable addition, but he was extremely skeptical as to the value of the resorcin added. It seemed strange that some patients could not take as much as three to five drops of chaulmoogra oil without complaining of nausea, while others could take one or two hundred drops without trouble. There was a marked difference in regard to the unpleasant effect, and Doctor Heiser had noted the same thing after hypodermic injections. Another conclusion was that locality and perhaps climatic conditions had much to do with improvement of the disease. Nearly every patient he had seen coming from the tropics or some country where the disease was endemic, had improved to a notable degree on coming to New York, even without treatment. In some instances where he had treated the patients with chaulmoogra oil, he was doubtful whether the improvement was due to the oil or to the change of climate, but after observing some of those who had been here for a long time without further improvement, he reached the conclusion that the improvement was due mainly to the oil. He also concluded that there was little or no fear of leprosy spreading in the city of New York. His views in this respect might differ from those of Doctor Heiser, but they should remember that there had been lepers here by the score for the past forty years or more, living in hotels and tenements, travelling in the trolley cars, and being treated in the hospitals, without any local increase in their number except from freshly imported cases. If the disease was going to spread from the mere presence of lepers, the fact should have been noted by this time. It might be all right and necessary in the Philippines, in New Orleans, and wherever leprosy was endemic, to segregate all those affected; but the hue and cry made here over some poor Chinaman by the newspaper men was absurd.

The fears of the public and of the profession that the disease might get a hold and spread in New York were groundless. In fact, the fear of leprosy in this city had done more real harm than the disease itself had done in the past or was likely to do in the future, even without compulsory segregation.

In regard to the psychological treatment of leprosy, Doctor Fox considered it important and generally neglected. The average doctor who examined a case of leprosy usually wore a long face and told the patient that he would do all he could. They could readily imagine the effect of such talk. They all knew that in general practice the mere presence of a trusted physician in the sick room often did the patient far more good than the prescription. In like manner a few words of cheer to a patient who was naturally worrying over the name of his disease and the assurance that leprosy was not necessarily incurable, would always improve his mental condition, which was highly important and acted as a most valuable adjunct to any plan of treatment. While leprosy might be fatal in a great many instances, it was also true that many persons did not die of the disease, but were simply scared to death. The treatment of lepers by some of the health officers, if reports were true, was an outrage. Let them imagine being told that they had leprosy, taken from home and friends, placed in some out of town shanty, and had their food poked in to them through a window on a long board by some health official afraid of getting the disease. It was easy to imagine that their symptoms would not improve, and that they would soon die under such treatment, whether they had leprosy or not. He sincerely wished that some wealthy man or woman would endow, not a hospital, but some large model farm where the lepers of New York city could be sent, not under compulsion, but at their own desire, where they could have plenty of outdoor work, enjoy life, and forget the name of their trouble. This alone would do a vast amount of good, and combined with the approved modern methods of treatment, would tend to teach the public the lesson that it needed to learn, viz., that leprosy was not the horrible and incurable disease which the average newspaper reporter so delighted to portray.

Doctor Fordyce said it had been a great delight to him to hear Doctor Heiser's very scientific and modest presentation of the subject; his great experience with the disease and his careful study of it entitled him to speak with authority. It would be foolish, therefore, to say anything in criticism of the method which the doctor had devised, unless they had equal experience in its use. Many methods of treatment had been employed by men dealing with leprosy in countries where it was endemic with more or less success. Ten years ago, while visiting Bergen, Norway, he had interviewed Doctor Lie, who was in charge of the leprosy hospitals in that city. In reply to an inquiry as to whether he had any methods of successfully treating the patients, Doctor Lie had replied that he had none, but simply treated the symptoms according to indications. Chaulmoogra oil had been used by physicians dealing with leprosy in all parts of the world, but no one heretofore had devised a method which had given the results obtained by Doctor Heiser. The reactions produced in leprous lesions and the general reaction which the patients experienced, were an indication that the drug had a specific effect on the lesions. This reaction impressed him as analogous to the Herxheimer reaction sometimes seen in syphilitic lesions after the administration of salvarsan, mercury, or the iodides. Another argument brought forth was the loss of the staining properties of the bacilli and the rapid involution of the leprous lesions by the chaulmoogra oil given in this way. It was true that many leprous lesions underwent spontaneous involution just as analogous lesions did in syphilis or in other members of the group of the infectious granulomata, but the involution of lesions which occurred spontaneously was much slower than after the chaulmoogra oil treatment. He did not care at this time to discuss the question of segregation of lepers, but he agreed that lepers would be better off if segregated under good conditions than if allowed to go at large as they were now.

Doctor Heiser, in closing, said that he had referred to the question of segregation of the lepers parenthetically, and not as a part of the paper. He had no intention of proposing a question of that kind before the association, but had thought it might be of interest to relate a few of their experiences in that direction. He had studied the question of the transmission of leprosy more than he had ever studied any other problem. When he first became associated with the leper question in the Philippines, he had some theories with regard to the transmission of the disease; but he had tested these theories, as well as those of others, and found them all wanting. So far as he was aware, there was no satisfactory explanation as to the manner of transmission; but in his experience, which involved many thousands of cases in different parts of the world, he had not found a case that was not associated with a previous case, so it would seem that direct or indirect human contact of some kind was necessary. In other words, he knew of no case of leprosy originating in a community in which there was not a previous case, or the person affected had not come from another district in which leprosy prevailed. As to its not being a danger in the United States, how could any one speak definitely upon that subject? When they first went to the Philippines, they were told that there was practically no cancer there. He consulted many old practitioners and they said cancer occurred so seldom as to be negligible. It was not a disease of the tropics. After large modern hospitals were opened and the diagnosis of disease was done on more scientific lines, cancer was found to be as prevalent in the Philippines as in the United States or Europe. It would seem that a similar experience might be had with leprosy in the United States.

Since he had returned to this country, he had been trying to obtain a trustworthy estimate as to the number of lepers in the United States, and had been surprised to learn that no such data were available. Some guesses had placed the number between several hundred and several thousand. Under such circumstances who could state with reasonable certainty whether the disease was increasing or decreasing?

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

The Involuntary Nervous System. By Walter Holbrook Gaskell, M. A., M. D., F. R. S.; Author of The Origin of Vertebrates, etc. With Colored Plates. Bombay, Calcutta, and Madras: Longmans, Green & Co., 1916. Pp. ix-178. (Price, $1.80.)

This is the first volume of a new series of monographs on physiology, under the general editorship of Dr. Ernest H. Starling. Each of the volumes announced is to be the work of one who has himself made special contribution to our present knowledge of the particular subject on which he writes. The volume before us is by Doctor Gaskell, who for forty years made a special study of the sympathetic nervous system, and who, therefore, was able to write authoritatively upon the subject. This little book of 160 pages is a model of what such a work should be. The first chapter is historical, and shows in an interesting manner the rise, predominance, and fall of the theory of Bichat on the sympathetic nervous system, which was accepted for a long period of time. Adequate recognition is made of the work of other scholars, and there is an ample bibliography appended to the volume. The last chapter contains a brief summary, and (together with the first chapter) should be read by all students of physiology. The other chapters are on: The characteristic motor functions of the nerve cells belonging to the thoracicolumbar, bulbosacral, and midbrain outflow of connector nerves; the inhibitory nerves; the rhythmic and peristaltic movements in the involuntary muscles of the vertebrate; the innervation of glandular structures; the connector neurons of the involuntary nervous system; and the phylogenetic origin of the sympathetic nervous system. It is to be hoped that the remaining volumes of the series will not be delayed unduly, and that they will be of the same handy size as the present instalment. The work of the printers and publishers is first class throughout, in pleasing contrast with some of the sloppy work which we have noticed of late.

A Guide to Gynæcology in General Practice. By Comyns Berkeley, M. A., M. D., M. C. (Cantab.), F. R. C. P. (Lond.), Obstetric and Gynæcological Surgeon to the Middlesex Hospital and Surgeon in Charge of its Military Hospital at Clacton-on-Sea; Surgeon to the Chelsea Hospital for Women; Senior Obstetric Surgeon to the City of London Lying-in Hospital, etc., and Victor Bonney, M. S., M. D., B. Sc. (Lond.), F. R. C. S. (Eng.), M. R. C. P. (Lond.), Assistant Obstetric and Gynæcological Surgeon to the Middlesex Hospital and Surgeon in Charge of its Military Hospital at Clacton-on-Sea; Surgeon to the Chelsea Hospital for Women and the Hounslow Hospital, etc. London: Henry Frowde (Oxford University Press) and Hodder & Stoughton, 1915. Pp. xxiii-452. (Price, $6.50.)

In this book, intended for the general practitioner, a special attempt has been made to overcome difficulties in diagnosis arising from the varying aspects under which given affections may present themselves in actual practice. Clear distinction is made between the various forms under which certain conditions may be met with owing to different causative factors, and the therapeutic indications in each are separately discussed. Part I is occupied with the methods of gynecological examination; Part II with the significance of symptoms, e. g., amenorrhea, uterine hemorrhage, abdominopelvic pain, backache, dysmenorrhea, symptoms referable to the urinary tract, etc.; Part III with the interpretation of physical signs, such as abdominal tenderness, abdominal swelling, the size of the uterus as noted on vaginal examination, uterine displacement, abnormalities of the vulva, etc., and Part IV with the treatment of the various conditions previously taken up. No details of operative technic are given, these being taken up in the textbook of gynecological surgery, by the same authors. From the standpoint of diagnosis the work is all that can be desired by the practitioner as a handy manual. The illustrations in Parts I and II are numerous and helpful. In Part IV, however, although many remedial measures are mentioned, there seems to be in places a lack of specific details as to the nonoperative therapeutic procedures (other than the use of drugs) recommended. The indications for operative intervention are clearly given throughout, and the practitioner will be in no doubt on this score. Part V, dealing with the medicolegal aspects of gynecology, though based on English law, is of particular utility, covering a field which few textbooks enter into, and yet with which the physician is frequently concerned. Such questions as nullity of marriage, rape, criminal abortion, evidences of present or remote pregnancy, foreign bodies, and claims for compensation are succinctly discussed in this final portion of the text. The index is very full, occupying thirty-five pages.

Practical Physiological Chemistry. A Book Designed for Use in Courses in Practical Physiological Chemistry in Schools of Medicine and of Science. By Philip B Hawk, M. S., Ph. D., Professor of Physiological Chemistry and Toxicology in the Jefferson Medical College of Philadelphia. Fifth Edition, Revised and Enlarged. With Two Full Page Plates of Absorption Spectra in Colors, Four Additional Full Page Color Plates and One Hundred and Seventy-two Figures, of Which Twelve are in Colors. Philadelphia: P. Blakiston's Son & Co., 1916. Pp. xiv-638.

This standard textbook, now in its fifth edition, has been thoroughly revised and in part rewritten, so that it is more than ever indispensable as a reference book for the internist, the dietitian, and the laboratory worker. The new chapters deal with nucleic acids and nucleoproteins, gastric analysis, intestinal digestion, blood analysis, and metabolism. To economize time and effort the important laboratory procedures have been set forth in black face type. The latest and best methods of quantitative analysis have been introduced. The nephelometer has been discussed and nephelometric methods have been described. The book is enhanced in value by its virtues of intelligent omission and wise selection in tests and procedures. The letter press is admirable despite the weight of the paper, and thirty-five new illustrations give added value to the text.

Interclinical Notes

According to the *Medical Summary* for June, 1916, the new edition of Osler in five volumes just out—$25—tells one everything except how to treat the sick.

* * *

Protagonists of the bobtail spelling, the *Journal A. M. A.* in particular, prove too much when they aver that appendectomy is a better because shorter form than appendicectomy. The latter form is as correct as a hybrid can be, and to correctness scientific men should be slaves. All the arguments for appendicectomy apply with equal force to appenditis as a substitute for appendicitis. But why argue seriously with people who can calmly mutilate the spelling of the words of a dead language?

* * *

A curious sentence in the *Century* for July is: "He looked at the fire and lighted a cigarette, a very unusual habit for him." It occurs in a story called Burney's Laugh, by Stacy Aumonier. The idea of an unusual habit is quaint.

* * *

The *Survey* for May 20th gives attention to the recent State Conference of Charities and Corrections held at Hoboken, April 30th to May 2d. Speaker after speaker at this conference pointed out that not only were physical handicaps responsible for much dumbness and stupidity, but that many a mental quirk and peculiarity was due to a "wrong mental attitude toward life." Expert treatment was as necessary, they added, for "complexes" which blot straight mental vision as are correct glasses for bad physical vision. Thus Dr. Pearce Bailey, of the New York Neurological Institute, divided "thinking" into two classes—"logical thinking" and "wish and fear thinking." The latter kind must be controlled, he urged, sometimes by the aid of a physician, if a person is going to adjust himself to life. Doctor Bailey recommended a central examining plant in every city for adolescent children who were shiftless and purposeless or had some twist in their mental makeup.

We note in the articles on religion in *Current Opinion* for June, that Christianity seems to command no more respect or space than many another cult—a sign of the times, we presume. The department of literature and art in this periodical is extremely well done; this month there is a capital discussion of the humorous French journals issued from the trenches and a selection of astonishingly good poetry.

* * *

Veiled Island, by Marjory Morten, in the July *Century*, is a collection of material for a story rather than a formal tale; the entire personnel is dumped just when the problem presents itself. They Both Needed It, is a singular psychological study of a boy and his father, by Fanny Kemble Johnson. There is a charming essay, Neighbors, by Eugene Wood, which contrasts the social conditions of town and country, not always to the advantage of the latter. The illustrations are beautiful, including a frontispiece from a miniature of the Princess Marie-José of Belgium. The *Century* is always decorative as well as entertaining and instructive.

* * *

In the *Medical Review of Reviews* for June the charge is made that a physician was responsible for all the damage done by the four per cent. cocaine snuff once known as Doctor Cole's Catarrh Cure—Doctor Cole presumably being the depraved physician in question. There never was a Doctor Cole; the originator and owner of this preparation, as a matter of fact, was neither a physician nor a druggist; he was a manufacturer of several patent medicines and invented Doctor Cole, simply to secure what he considered a desirable alliteration. Thus one slur on the profession is disproved.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers in the United States Public Health Service for the seven days ending June 21, 1916:

COLLINS, G. L., Surgeon. Relieved from special duty at Pittsburgh, Pa., and ordered to return to Washington, D. C.

HURLEY, J. R., Passed Assistant Surgeon. Granted two days' leave of absence on account of sickness, June 12 and 13, 1916.

KEMPF, GROVER A., Assistant Surgeon. Granted one day's leave of absence on account of sickness, June 10, 1916.

KRULISH, EMIL, Passed Assistant Surgeon. Directed to proceed to Juneau, Alaska, to assist in organization of hospital for Board of Education, Department of the Interior.

OAKLEY, J. H., Surgeon. Granted three days' leave of absence from June 17, 1916, under paragraph 193, Service Regulations.

SAFFORD, M. V., Assistant Surgeon. Granted two days' leave of absence, June 19-20, 1916.

WHITE, M. J., Surgeon. Directed to attend a Better Community Conference at the University of Illinois, Urbana, Ill., June 20-21, 1916.

Board Convened.

Senior Surgeon Fairfax Irwin and Passed Assistant Surgeon C. P. Knight designated as members of a board to revise the regulations of the Coast Guard governing the physical qualifications required for enlistment and reenlistment and for appointment, to meet at the Treasury Department, Washington, D. C., June 21, 1916.

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending June 17, 1916:

BENTON, F. L., Surgeon. Detached from duty at the Naval Station, Key West, Fla., and ordered to duty with the expeditionary forces, Santo Domingo.

CARSON, V. H., Assistant Surgeon. Detached from the naval recruiting station, New York, N. Y., and ordered to duty with the expeditionary forces, Santo Domingo.

FREEMAN, ARTHUR, Assistant Surgeon. Ordered to duty at the Navy Yard, New York, N. Y.

HARPER, JOHN, Assistant Surgeon. Detached from the Navy Yard, New York, and ordered to the Minnesota.

ROYSTER, H. A., Assistant Surgeon, Medical Reserve Corps. Commissioned from May 15, 1916.

ZALESKY, W. J., Passed Assistant Surgeon. Ordered to naval recruiting station, Brooklyn, N. Y.

Births, Marriages, and Deaths

Married.

BAGNALL-SALMON.—In Mountain Lakes, N. J., on Saturday, June 3rd, Dr. Elmer S. Bagnall, of Boston, and Miss Aida H. Salmon.

BOGLE-WOODWARD.—In Santa Rosa, Cal., on Saturday, June 3rd, Dr. Samuel S. Bogle, of San Francisco, Cal., and Miss Bess Woodward.

DWYER-COUIG.—In Boston, Mass., on Wednesday, June 14th, Dr. John E. Dwyer, Jr., of Cambridge, Mass., and Miss Margaret D. Couig.

GARVIN-MEYER.—In Cleveland, Ohio, on Friday, June 16th, Dr. Justin Garvin and Miss Charlotte Meyer.

GOLDEN-LEGARDE.—In Stoughton, Mass., on Wednesday, June 14th, Dr. Joseph F. Golden and Miss Stella K. Legarde.

GREENMAN-SNOW.—In Kankakee, Ill., on Monday, June 5th, Dr. Ernest N. Greenman, of Sheldon, Ill., and Miss Portia Snow.

HERBST-KOCH.—In Allentown, Pa., on Monday, June 12th, Dr. William Frederick Herbst and Miss Florence L. Koch.

JONES-KROME.—In Alton, Ill., on Saturday, June 3rd, Dr. Fred Wade Jones and Miss Mary Krome.

MCCANN-BUCKLEY.—In Brockton, Mass., on Thursday, June 15th, Dr. Charles D. McCann and Miss Rose Buckley.

PERKINS-PHILLIP.—In Yonkers, N. Y., on Thursday, June 15th, Dr. Edward Carter Perkins and Miss Georgiana M. Phillip.

SPICER-LEYDIG.—In Cumberland, Md., on Thursday, June 15th, Dr. Joseph H. Spicer and Miss Leah Leydig.

STONE-WILLIAMS.—In Brookline, Mass., on Thursday, June 15th, Dr. Eugene P. Stone and Miss Eleanor Williams.

WELDON-ABBERTON.—In Bridgeport, Conn., on Saturday, June 17th, Dr. Edwin B. Weldon and Miss Helen Abberton.

Died.

AITKEN.—In Brooklyn, N. Y., on Sunday, June 18th, Dr. Lawrence T. Aitken, aged thirty-one years.

BILLS.—In Alkegan, Mich., on Saturday, June 10th, Dr. Walter H. Bills, aged seventy-one years.

CLEVELAND.—In Fargo, N. D., on Tuesday, May 30th, Dr. William P. Cleveland, aged sixty-eight years.

COOPER.—In Brownsville, Tenn., on Friday, June 9th, Dr. Thomas W. Cooper, aged eighty-seven years.

CREASY.—In Rock Glen, Pa., on Tuesday, June 13th, Dr. Lloyd S. Creasy, aged fifty-three years.

DRYDEN.—In Morley, Colo., on Monday, June 5th, Dr. Frederick G. Dryden.

GILMAN.—In Boston, Mass., on Saturday, June 17th, Dr. Eugene Albert Gilman.

HOKE.—In Richfield Springs, N. Y., on Friday, June 16th, Dr. Fenimore C. Hoke, aged forty-five years.

KENDALL.—In Pittsburgh, Pa., on Saturday, June 10th, Dr. William H. Kendall.

KENDIG.—In Philadelphia, Pa., on Saturday, June 17th, Dr. Rudolph Kendig, aged fifty-one years.

LEARY.—In Lowell, Mass., on Sunday, June 11th, Dr. James E. Leary, aged forty-three years.

MONTGOMERY.—In Charleston, Ill., on Wednesday, June 14th, Dr. J. R. Montgomery, aged sixty-two years.

MUNSON.—In Brooklyn, N. Y., on Tuesday, June 13th, Dr. Lansing Munson, aged eighty-two years.

MURTLAND.—In New York, on Thursday, June 15th, Dr. Samuel Murtland, aged sixty-six years.

RIEGER.—In Kansas City, Mo., on Wednesday, June 14th, Dr. Joel H. Rieger, aged sixty-six years.

SWEENEY.—In Jeffersontown, Ky., on Friday, June 16th, Dr. John Tyler Sweeney, aged thirty-seven years.

WHITE.—In South Glens Falls, N. Y., on Monday, June 19th, Dr. J. Seward White, aged fifty-nine years.

WILLIAMSON.—In Tuscaloosa, Ala., on Friday, June 16th, Dr. James Lewis Williamson.

WILLARD.—In Hartford, Conn., on Friday, June 16th, Dr. Frederick Buel Willard, aged forty-three.

EXOPHTHALMIC GOITRE.*

With Special Reference to the Etiology and Treatment with Radium.

BY W. H. B. AIKINS, M. D.,
Toronto, Ont.

Exophthalmic goitre is referred to in literature under several different names, including Graves's disease, Basedow's disease, and Parry's disease, and the designation of hyperthyroidism has recently been applied to it by some observers. This latter term, however, can scarcely be regarded as an appropriate one, as it is now generally assumed that hyperthyroidism, although it probably plays a certain role in the causation of the disease, is not by any means the only etiological factor. The designation of exophthalmic goitre also has the disadvantage that the assumption on which it is based, namely, that exophthalmos and enlargement of the thyroid are invariably present, has now been shown to be without foundation, as one or both of these symptoms may be absent in an otherwise typical case; but it has been so generally adopted that I propose to use it.

In spite of the fact that there is probably no condition in regard to which such extensive investigations, both clinical and experimental, have been made during the last few years, and notwithstanding the amount of literature which has accumulated upon the subject, the etiology of exophthalmic goitre still remains obscure, although considerable light has been thrown upon it. The two chief theories which have been advanced may be considered under the following headings: 1. The glandular theory; 2. the neurogenic theory.

1. THE GLANDULAR THEORY.

The theory of Mœbius was for a long time very generally accepted as a sufficient explanation of the symptoms of exophthalmic goitre. It assumes that it is due to a primary functional disturbance of the thyroid, resulting in the production of an excess of secretion, which saturates the organism, and causes the symptom complex. Many writers now consider it probable that abnormalities of the other endocrinous glands, such as the thymus, suprarenals, hypophysis and ovary, also play a more or less important part in the etiology of the condition.

2. THE NEUROGENIC THEORY.

The neurogenic theory does not negative the glandular theory, but is complementary to it, there still being difference of opinion whether the glandular or the neurogenous disturbance is to be regarded as the primary one. Feeding with thyroid substance, both experimentally and by the administration of thyroid tablets in man, sometimes produces the typical symptoms, while in other cases it fails to do so, even if continued for a prolonged period. This indicates that the disease cannot be regarded as a pure hyperthyroidism, but that, in addition to an abnormal secretory function of the thyroid, a predisposing factor of some kind is essential, and the facts which are now at our disposal lead to the assumption that this predisposing factor is to be sought for in a primary defect or injury to the central nervous system. This hypothesis is confirmed by the comparative frequency of the disease in neurotic persons and those with a neuropathic heredity, as manifested by the occurrence of diseases such as insanity, hysteria or epilepsy in other members of the patient's family. The predominance of symptoms referable to the nervous system in the clinical picture is also confirmatory. Bumsted (1) emphasizes the fact that direct inheritance of the disease itself is not so uncommon as is generally supposed. He cites Rosenberg's case, in which the patient's grandmother, father, two aunts, and two sisters had suffered from exophthalmic goitre, and Oesterreicher's statement that in a family of ten children eight suffered. Bumsted himself has had four sisters under his observation during the last five years. Two of them have severe exophthalmic goitre and a third early symptoms, while the fourth manifested symptoms when she had been for some time at home with her sisters after leaving school.

Although it has not yet been definitely proved, it appears probable that abnormalities of the other endocrinous glands play a part in the production of the symptoms. This applies more especially to persistence and hyperplasia of the thymus, which has been observed in a large proportion of the cases which have been examined post mortem, and is described by the French writers as rejuvenescence of the thymus. Capelle and Bayer (2) found enlargement of the gland in forty-three of sixty autopsies (seventy per cent.), Matti (3) in seventy-five per

*Read at a meeting of the Ontario Medical Association June 2, 1916.

cent. of 133 autopsies, Berry (4) in 100 per cent. of the autopsies that he has made, and Klosé (5) goes so far as to say that exophthalmic goitre never occurs without enlargement of the thymus. Capelle and Bayer believe that in most cases the symptoms result from abnormal function of the thyroid, which is supplied by the sympathetic nervous system, and the thymus which is supplied by the vagus. Some writers explain the symptoms, not by disease of the thyroid, but of the thymus, and Garre (6), who now operates on the thymus in every case, states that its removal causes the disappearance of Garre's characteristic blood picture. Hart (7) is inclined to agree with this opinion, and believes that the thymus of itself is capable of causing the symptoms usually ascribed to the thyroid. He therefore assumes secondary disease of the thyroid, due partially to persistence of the thymus and partially to constitutional anomalies, above all, lesions of the nervous system. On the other hand, Kocher (8) says there is no proof that typical exophthalmic goitre can be induced by the thymus alone without hypersecretion of the thyroid, but that it is possible that hyperplasia and persistence of the thymus predispose to it. He finds that an enlarged and persistent thymus is particularly common in certain districts and certain families, in which it is seen both with and without symptoms of exophthalmic goitre. He accordingly regards it as merely a regional familial late involution, dependent upon congenital or possibly constitutional peculiarities, and not as a direct cause of the disease.

There seems reason to believe that other internal secretion glands have some influence. In exophthalmic goitre Kocher found general hyperplasia of the lymphoid organs and proliferation of ectopic lymphoid tissue, involving the suprarenals, and ovaries, and more rarely the pancreas. The frequency of pigmentation of the skin suggests the possibility of an influence of the suprarenals, while the greater frequency of the disease in women points to the influence of ovarian secretion. It is a well known fact that there is a predisposition to the onset of exophthalmic goitre at puberty and the cessation of menstruation, and to exacerbations of the already existing disease during menstruation and pregnancy.

While there is evidence that an excess of thyroid secretion is of importance in giving rise to the symptoms of exophthalmic goitre, there seems reason to believe that it does so only if some predisposing factor is present, and that this primary predisposing factor consists in an injury to the nervous system. The secretion of the thyroid gland consists of iodine, an albumin body, and a group of proteins, and described collectively as iodothyreoglobulin. This combination appears to possess specific characteristics, which none of its constituents possesses in itself, either alone or in combination with one of the others. Oswald, who has made extensive investigations in this connection, states that iodothyreoglobulin increases nerve tonus and the excitability of the nervous system, and also favors metabolism and degeneration of the albumin and fat. These properties explain the clinical pictures of myxedema and hyperthyroidism, thyroid secretion in the former being reduced or abolished, and in the latter increased. Oswald (9) points out the significance of the fact that symptoms of exophthalmic goitre do not invariably develop in response to saturation of the organism with iodothyreoglobulin, and therefore concludes that the exothyroid contributory factor must be something more than a mere predisposition. Oswald does not regard the saturation of the organism with iodothyreoglobulin as primary, but as a result of increased innervation of the gland and excessive flow of blood through it, in which the nervous system plays the primary role. A so called vicious circle is thus established, the excessive amount of secretion poured out increasing still further the tonus and excitability of the nervous system, and the latter in its turn reacting on the thyroid, and intensifying its innervation and thereby its secretory activity.

Constitutional diseases, such as diabetes, gout, and obesity, are not infrequently present in these cases, and careful inquiry will often elicit the information that the patient has for a long time suffered from severe nervous and psychical disorders, sometimes dating back to childhood. We find that long before the appearance of the typical symptoms the patient has been nervous, unduly excitable, irritable, and "difficult," and has perhaps suffered from cardiac troubles. A very common statement in the anamnesis is that there is intolerance for cocaine, as manifested on the extraction of a tooth. The general conclusion seems to be that, whatever part the thyroid and other internal secretion glands play in the setting up of the pathological process, injury to the nervous system is by far the most important etiological factor.

Exophthalmic goitre may follow acute diseases, such as typhoid, rheumatism, diphtheria, and especially influenza. Bialokur reports its occurrence in twenty-seven of 337 cases of pulmonary tuberculosis, and its stimulation in the early stages of the symptoms of the latter disease has sometimes led to an erroneous diagnosis. It is not uncommon in chlorosis. McCarrison's (10) extensive researches in relation to endemic goitre, in the course of which he obtained good results from vaccines prepared from organisms isolated from goitre, suggest the possibility that the enlargement of the thyroid in exophthalmic goitre may also be due to some non-specific infection.

TREATMENT.

The treatment of cases of exophthalmic goitre is always difficult, and demands a maximum of good judgment on the part of the physician if he wishes to obtain a successful result without referring them to the surgeon for thyroidectomy. It is a mistake to assume that the condition is practically incurable by medical treatment, and after a careful study of its results in the hands of various writers, including Hale White (11) and Mackenzie (12), Solis Cohen (13) concludes that there is a reasonable prospect of recovery in about seventy-five per cent. of the cases, which is about the same proportion as that allotted to surgery in the hands of competent surgeons. At the same time there is no doubt that for some cases surgery is imperative, and in this respect

each case should be judged on its own merits. Whatever the treatment adopted, it is exceptional for all the symptoms to disappear completely, but most authorities agree that we are justified in speaking of cure if the general condition and strength are maintained, and the symptoms are relieved to such an extent that the patient is able to resume her ordinary occupation.

The brief account which has been given of the various hypotheses in regard to the causation of the disease makes it obvious that in the treatment it is essential to adopt measures tending to reduce excessive vascularity of the gland, thereby diminishing secretion and the tendency to hyperthyroidism. With this object in view it is absolutely necessary to secure for the patient the most complete bodily and mental rest obtainable under the circumstances, thus removing the stimulating effect on the thyroid of exercise and excitement. In some of the slighter cases a simple rest and isolation cure alone may relieve the symptoms, and if persevered in for some considerable time result in subsidence of the enlargement of the gland. During the first stage of the treatment rest should be so complete that it should not even be disturbed by the administration of medicaments. The length of time during which it is advisable for the patient to remain in bed varies in accordance with the progress of the case. The best guide in this respect is the condition of the pulse. When it has remained regular and practically normal for three or four weeks, the patient may be allowed to rest on a sofa in the room for an hour or so daily, and subsequently increase the amount of exertion very gradually day by day. The benefit of the rest cure is likely to be greater if it is possible to take it in the country, preferably in a bracing climate, and away from the ordinary surroundings of the patient.

Defective nutrition is commonly associated with this disease, and therefore a liberal and nutritious diet, similar to that often recommended in pulmonary tuberculosis, is frequently indicated. Foods rich in extractives should be avoided, the diet consisting chiefly of milk and cereals, together with fruit and the more easily digested vegetables. It should be borne in mind, however, that gastric hyperacidity is present in not a few of these cases, and that under such circumstances it is advisable to forbid acid fruits.

MEDICAMENTS.

As regards the medicaments which have been recommended, their name is legion, and the most contradictory opinions are given by different writers as to the efficacy of most of them. Opinions differ as to the advisability of giving hypnotic drugs, such as veronal, sulphonal, and trional. Some writers recommend them for the purpose of procuring sleep and lessening excitability, while others emphasize the fact that in neurotic cases of this description the drug habit is easily formed, and not so easily given up. Williams (15) thinks that the only sedative drug permissible is aspirin. The benefit sometimes derived from belladonna is due rather to its property of controlling glandular secretion than to its sedative qualities.

Of the bromides the only preparation which has been found useful is hydrobromide of quinine, which is highly recommended by Miller (16), Forschheimer (17) and others. Bumsted states that with it he has been able to cure several cases which had previously proved refractory to all other forms of treatment, including operation, and that one of its advantages is that it can be taken for months together without bad effects. In my own practice I have found that the most effective drug treatment is the administration of this preparation in the form of capsules or cachets, each containing five grains of hydrobromide of quinine and one grain of ergotin, the dose being given three times daily.

Leigh Watson (18) reports beneficial results from the injection of one to four c. c. of a thirty to forty per cent. solution of quinine and urea in fifty cases of exophthalmic goitre, the dose being repeated every third day. Two severe cases remained free from symptoms eighteen months after the last injection, and sixteen have been free from symptoms for one year.

On the assumption that exophthalmic goitre is more common in districts in which the water is deficient in lime, treatment by the administration of calcium salts has been recommended. Campbell (19) states that during the last eighteen months he has been in the habit of treating his cases in this way, and has had better results than from any other form of medication. He does not suggest that it should be the only treatment, but that it should be combined with any other form of treatment selected. He gives a dose of ten grains of chloride of calcium daily.

In view of the liability to digitalis toxemia in toxic conditions of the thyroid, many writers emphasize the desirability of avoiding the use of this and other cardiac drugs, except in cases in which special indications, similar to those in organic disease of the heart, are present. Weiland (20) points out that such indications are absent in the cases in which some surgeons recommend a dose of digitalis before operation, and that they should therefore be included in the category in which the drug is contraindicated.

ORGANOTHERAPY.

Some writers state that they have obtained satisfactory results from administration of extract of the thymus gland, but the reports as regards treatment by organotherapy, including the administration of thyroid substance, are on the whole not very favorable, and do not compare with the brilliant results obtained in cretinism and myxedema from organotherapy. Serum from thyroidectomized sheep and milk from thyroidectomized goats are sometimes used in the forms of preparations known as rodagen, thyroidectin, and antithyroidin, and have been found useful in some cases.

RÖNTGEN RAYS.

The fact that x rays are known to have a selective effect upon glandular tissue, justifies the assumption that their use may be beneficial in exophthalmic goitre, and they have accordingly been extensively used, both alone and in combination with surgery.

Satisfactory results are reported by several writers, and Kienbock (21), Nagelschmidt (23) and others go so far as to say that no operation for this condition should be undertaken without preliminary treatment by x rays, and that if this procedure were universally adopted it would be likely materially to reduce the operative mortality of exophthalmic goitre. Belot (23) is of the opinion that even in the so called abortive cases in which struma is absent, the rays have a favorable influence on excessive and dysfunction (deficient or perverse function) respectively of the glands of internal secretion, even if these abnormalities are not associated with appreciable enlargement. Dr. Dawson Turner (24) reports successful cases, in which application of the x rays was followed by diminution in the size of the thyroid and subsidence of the symptoms. This retrogressive process was associated with atrophy of the secretory epithelium and interstitial and extracapsular fibrosis.

RADIUM TREATMENT.

Clinical experience shows that many cases do not respond satisfactorily to any of these methods, and in these refractory cases I have found the employment of radium to be of decided benefit. Abbe, of New York, first used radium successfully in exophthalmic goitre, and his favorable experience of its results has been repeatedly confirmed by other writers. The experiments of Victor Horsley and Finzi (25) show that the most constant changes after the application of radium affect the blood and lymph vessels. My own clinical experience shows that, when applied over the thyroid, the more penetrating radium rays diminish the vascularity and reduce the secretion of the gland.

Dawson Turner, who has had very favorable results, thinks that radium has two definite advantages when compared with the x rays, i. e., 1, the possibility of giving definite doses; 2, the fact that it can be applied without noise or excitement, while the patient remains in bed.

The following cases will serve as examples of the benefit to be derived from the use of radium rays in exophthalmic goitre:

Case I.—Mrs. M., aged thirty-one years; married; two children. Five years before coming to me, she noticed enlargement of the thyroid and had used local applications, probably iodine, with no effect. A month before she consulted me the growth had increased to such an extent that it was spreading to the lateral lobe. She had suffered from difficulty in breathing, and discomfort on speaking or swallowing. Recently her appetite had been bad, and she had felt tired, nervous, and disinclined for work. On examination, the thyroid was found to be definitely enlarged and pulsating, especially its middle and right lobes, the neck being fifteen inches in circumference. The pulse rate was 88, accelerated on slight exertion. The condition appeared to be an early stage of exophthalmic goitre.

Three thyroidectin tablets, each containing five grains, were given daily, and in addition a radiation of 100 mg. hours was given with a large radium plaque. A week later the circumference of the neck had diminished to fourteen inches, the pressure symptoms were better, and the patient felt better. Five weeks after the beginning of the treatment the neck was thirteen inches in circumference, the tumor had almost disappeared, the patient no longer complained of nervousness, and she has remained well ever since.

Case II.—A young unmarried woman of twenty-one years had for a year been so nervous, excitable, and changed in disposition that her parents feared for her mental condition. A physician was consulted, but apparently he did not suspect the real nature of the disease. When she first came under observation, she was in a highly nervous condition, with marked tremor, cardiac rapidity, and enlargement of the thyroid, the circumference of the neck being fourteen inches. The treatment adopted was rest in bed, with an ice bag applied over the heart, and the administration thrice daily of a quinine hydrobromide capsule (five grains hydrobromide, ergotin, one grain). The thyroid gland was subjected to a heavy exposure to radium rays. Three months later the neck was only twelve and one half inches in circumference, and the tachycardia and nervous symptoms had disappeared. Further radium treatment has since been given; she has now continued well for more than two years, and has been able to resume her normal life.

Case III.—In this case, in a young woman, the circumference of the neck was sixteen and three quarter inches. When first seen, signs of hyperthyroidism were not marked, there being slight tremor, but no tachycardia. She was not treated by absolute rest until severe tachycardia suddenly developed, the pulse rate going up to 160, when she was at once put to bed with an ice bag over the precordia. Radium was applied to the thyroid, and in three months the neck measured only twelve and one half inches, the pulse rate at the same time becoming normal. She has remained well ever since, that is for over three years.

Case IV.—A married woman, aged thirty-five years, was referred to me by Dr. G. W. Smith, of North Bay. She had suffered for the previous five months from exophthalmic goitre, which developed six months after the removal of the ovaries. The thyroid gland was only slightly enlarged, but there was well marked tremor, and the pulse rate was 140. She had been treated at home by rest in bed, suitable diet and medication, together with other ordinary recognized measures of treatment, but without result. As a last resort she was sent to me for radium treatment. I prescribed absolute rest in bed with an ice bag over the precordium, and the administration thrice daily of hydrobromide of quinine (five grains, with one grain ergotin). In addition, heavy radiation was instituted of the thyroid. The improvement was marvellous. Within two weeks the pulse rate had dropped to 75, and nervousness had almost entirely disappeared. The patient was kept under observation for six weeks, when she went home in apparently normal health. When seen again, about six months later, there had been no return of the symptoms of hyperthyroidism, and I am informed that she continues well.

Case V.—A girl of nineteen years, referred to me by Doctor Clarke, of Bowmanville, Ontario, who presented the typical picture of Graves's disease. The thyroid was fairly prominent, the circumference of the neck being fourteen and one half inches. There was well marked exophthalmos, the pulse rate was 120, and the patient was very nervous. No benefit had resulted from all the ordinary measures of medical treatment, which had included the administration of hydrobromide of quinine and ergotin and of Mœbius's serum, together with absolute rest for some months. She was kept in bed with an ice bag over the precordium, the quinine and ergotin being continued. In addition an exposure of seventy mg. hours of radium was given over the thyroid. She went home and was not seen again for five weeks. At the end of this time the pulse rate was still 120, but the circumference of the neck was reduced to thirteen inches. She was further radiumized, and when seen again, two months later, the pulse rate had dropped to 76, tremor had disappeared, and the exophthalmos was scarcely noticeable.

This patient was last seen in September, 1915, when she had improved sufficiently to be able to do light housework. The neck measurement remained thirteen inches, and the pulse rate was 80. The effect of radium in this case was most marked, as before its employment no improvement whatever had resulted in the patient's condition.

Case VI.—An unmarried woman, aged forty-five years, manifested symptoms of exophthalmic goitre in March, 1915. She complained of a "sick nervous feeling," and marked tremor. The pulse rate was about 130. There was considerable improvement after a rest cure, but the slightest exertion brought about a return of the symptoms. She first consulted me early in October, 1915, when there was definite exophthalmos and tremor, the pulse rate ris-

ing to 120 on the least exertion. There was marked prominence of the left lobe of the thyroid, the neck measuring fourteen and one half inches. Hydrobromide of quinine and ergotin were given, with an ice bag over the heart. Radiation was applied over the thyroid. After receiving the treatment she returned to her home in the country. When next seen, on November 2d, she looked and felt very much better. The neck measurement was half an inch less, the pulse at no time exceeded 90, and the nervousness had disappeared. Further radiation was given.

In January, 1916, the patient returned for observation. The pulse was only 76 a minute, even and regular. The left lobe of the thyroid was still somewhat prominent, but the symptoms of hyperthyroidism had disappeared completely.

CASE VII.—In this case all the recognized symptoms of severe hyperthyroidism were present, with the exception of enlargement of the thyroid gland. The patient was a married woman of twenty-seven years. Protuberance of the eyes was first noticed after an attack of influenza in the spring of 1913, and subsequently dyspnea and palpitation. During the following winter, the symptoms diminished somewhat in severity, but after an attack of tonsillitis in March, 1915, she began to have attacks of vomiting, suffering from palpitation, and was easily excited or startled, the action of the heart becoming very rapid. In June, 1915, she was kept in bed for five weeks, when her pulse became normal. When see in August, 1915, there was no enlargement of the thyroid, but the eyes were prominent, and the pulse ranged from 84 to 120. Radiation was given over the thyroid, and in October she reported that she was much better, the pulse was steadier, and she had gained in weight. In January, 1916, after further treatment, she was able to take short walks and do light housework without disturbing the pulse, nervousness had nearly disappeared, and instead of having become a confirmed invalid she had become a normal young woman.

HYDROTHERAPY.

Hallevorden (26), whose article is based on 100 cases, has had excellent results from the hydrotherapeutic method recommended by von Winternitz, which consists of packings and demibaths. The treatment is always agreeable to the patient, and the pulse usually goes down on the application of the packing. With it he gives daily cold applications to the neck and back, and also to the heart if cardiac symptoms are prominent. The avoidance of exhausting and depressing baths is advisable. In slighter cases benefit is often derived from indifferent, salt or gaseous baths of comparatively low temperature. If fever is present, it should be treated by tepid full baths or cool full baths, in accordance with the indications. Tight collars and tight lacing should always be avoided.

CONCLUSION.

In conclusion, I should like to refer briefly to the psychological aspect of the condition, and its significance in relation to treatment. In view of the fact, which is now generally accepted, that injury of some kind to the nervous system is—even if not a primary factor—at least a very important factor in the etiology of exophthalmic goitre, and that as a rule symptoms referable to it predominate in the clinical picture, it follows that one of the essential objects in our treatment is to endeavor to relieve these nervous symptoms, and that therefore psychotherapy plays an important role. This being so, it is obvious that it is highly desirable that physicians who have not had much experience with neurotic and neurasthenic people, and consequently do not understand them and have no sympathy with them, should refrain from undertaking the medical treatment of cases of this kind, in which the psychic element is such an important feature.

134 BLOOR STREET WEST.

VAGINAL HYSTERECTOMY.*

Its Indications and a Method of Performing It.

BY JOSEPH C. TAYLOR, M. D.,
New York,
Professor of Gynecology, Polyclinic School and Hospital.

Vaginal hysterectomy is by no means an operation of recent origin. To the French belongs the credit of having given it a foremost place in gynecological operations. Péan was one of the first to take it up, and his work was followed up by Segond. At the time these gentlemen began to experiment, the mortality from abdominal operations was very high, running up to thirty per cent. in some instances, and it can readily be seen what an incentive there was to branch out in the vaginal direction. From almost the very first they were able to show a mortality in their cases not exceeding six per cent., which was considered in their time marvelous. They performed the operation by clamping progressively from below upward, and the majority of their deaths were due to the clamp which was applied to the ovarian vessel, causing either an erosion of the bowel or irritation sufficient to produce general peritonitis.

The operation has passed since that time through different stages of perfection, and many deviations from the original method have come into vogue, and some of them have passed out—for instance, the angiotribe which was brought over here by Tuffier and used at one time quité extensively. Later it was discarded because of the number of secondary hemorrhages which followed its use. Then came the ligation operation, where the ligation of the vessels progressed from below upward; this met with marked success, the main objection being that in purulent cases where the ligature on the ovarian vessel was placed in the field of suppuration, secondary peritoneal involvement followed. A very ingenious device was evolved by Doctor Skene whereby the vessels were clamped progressively and

*Read before the Section of Obstetrics and Gynecology, New York Academy of Medicine, February 24, 1916.

the tissue in the jaws of the clamps was cooked by means of wires in a platinum conductor underneath one blade of the clamp; this operation was particularly successful, as it sterilized the whole field, the only objection being the time required for the application of the clamps, the cooking of the tissues, etc.

Doctor Pryor, with whom I was formerly associated, was among the first really to establish the technic of division of the uterus into two parts and clamping progressively from above downward.

I do not wish to give the impression that I consider that every patient who has suffered from an infection of the pelvic viscera is a fit subject for vaginal hysterectomy. On the contrary, the larger proportion, especially in the young, should have the benefit of conservative work, even at the risk of a second operation later. There is, however, a certain proportion who have suffered, perhaps, repeated attacks of gonorrheal infection, often mixed, which has invaded all the pelvic viscera and rendered them functionless organs and a constant source of absorption of poisonous toxins. The uterus, generally considered to be damaged the least by gonorrheal infection, is often the seat of extensive tissue destruction, especially in mixed infection, as well as the other pelvic viscera. I have seen cases in which nearly one half of the uterine body had been destroyed, with a history of foul discharge extending over a period of weeks.

A pure gonorrheal infection does not as a rule produce such dire results in the uterine body as does one mixed with the colon bacillus. In the tubes and ovaries, however, the gonococcus causes extensive destruction of tissue, especially of the tubes and in often repeated attacks, as frequently seen in prostitutes, the ovaries as well have undergone cystic degeneration, are encased in adhesions, and are practically worthless, diseased organs which cannot be restored. I maintain that the uterus should be removed in these cases of badly affected annexa, as that organ in nearly all such cases is also diseased and will probably give trouble in the future if left in the body. Moreover, of what service can it possibly be without the annexa? If left in the body it is prone to shrink in size, become retroverted, and be a source of annoyance in the future. As to contraindications, in that large group of cases of young women who have been unfortunate enough to contract gonorrhea and have had their annexa affected thereby, it is my firm belief that ovarian conservatism should be attempted, even at the peril of a second operation.

In cases where the surgeon, upon careful examination, decides that the appendix is involved as well, the abdominal route should by all means be selected. The vaginal route is contraindicated in all cases of appendicular involvement or intestinal as well when situated in the abdominal cavity. This operation is not indicated in young women suffering from prolapsus uteri, but is confined to those who have reached or are about at the menopause.

Hysterectomy, vaginal or abdominal, is indicated in cases where the operator is satisfied by the history and by his examination that conservative treatment of the annexa is not possible, also frequently in cases where conservatism has been attempted and destructive processes have followed, and the symptoms and tissue changes, in place of abating, have continued until the health of the patient and her usefulness are jeopardized. I have achieved some of my best results in cases of this class.

There are many points to be considered in the selection of the route, in doing a hysterectomy for fibromyomata. First, the proportion between the size of the growth and the vaginal outlet, which varies at different times, for instance, the tissues of a younger woman are much more pliable than in one who has reached the climacteric and has never had children; in the latter type, vaginal hysterectomy is out of the question, especially if the growth is of considerable size. On the other hand, if the patient has given birth, the vaginal outlet will have been rendered lax enough to allow of the removal of a larger uterine growth by the morcellation method, which will be described later.

One of the main points in selecting the vaginal route is to discern whether the main bulk of the growth is in the pelvic cavity. If the growth is mainly in the pelvis, with the upper zone floating free, the vaginal route is preferable in skilled hands. On the other hand, in cases where the growth has been rapid, carrying the uterine body well up into the abdominal cavity, incision through the abdominal wall is preferable.

The vaginal method is efficient in intraligamentous and retroperitoneal growths, as they can be attacked by this method with less disturbance to surrounding structures. Vaginal hysterectomy is without equal in that class of cases we often meet in women who have passed the menopause and later have hemorrhages from a small fibroid situated near the endometrium, as a useless organ which has become a nuisance can be removed without danger and with comparatively little discomfort.

There is a class of cases which formerly were difficult to cure, and many and varied plastic procedures were devised to obtain relief, which vaginal hysterectomy renders easy of cure practically without risk. I refer to complete prolapse after the menopause. Often we see cases where the cervix is eroded even to a raw state, by the rubbing of the clothing against the protruding parts, and the annoyance and inconvenience cause the patient to become distracted and consider herself almost a useless member of society. The most gratifying of results is to restore such a woman to normal health and mental poise. Some care in the technic (to be described later) is necessary to restore the bladder to its normal position and function.

Vaginal hysterectomy is applicable in cancer of the uterus in only two conditions: 1. In cancer of the cervix where the disease is so far advanced that a Wertheim is unlikely to result in a cure and is deemed advisable for the relief of pain and the nauseous discharges. I might add that such cases have been successfully treated of late by first applying radium and later by performing a Wertheim. 2. Cancer of the fundus has been treated equally well, so far as results show, by the vaginal method as by the abdominal.

We might add to this list cases of epithelioma of

the cervix occurring in elderly women who are stout, or who have a tendency to cardiac or nephritic disease. The method differs from that of bisection, hereinafter described, in that the operation should be done *en masse*. The uterine arteries are first exposed and clamped, and an incision is made through them so as to free the lower zone of the uterus. The upper zone is then freed from the bladder and the ovarian vessels are clamped well out toward the pelvic brim and the whole mass is delivered intact through the vagina. Otherwise the technic and aftertreatment do not differ from the method now to be described.

The cervix is seized with a pair of bullet forceps and drawn down and then released to determine the vesicovaginal fold. Incision is made where the vaginal mucosa joins the cervical, across in front, and the mucous membrane is pushed upward. An area of very light tissue is encountered beneath the base of the bladder, and the finger readily pushes up through this to the reflexion of the peritoneum.

At this stage, the posterior lip of the cervix is grasped with a bullet forceps and drawn upward so as to disclose the junction of the posterior vaginal mucosa with the cervix, which is incised across. The two incisions, however, do not meet; about one eighth of an inch of tissue is left at each lateral angle, representing a point which corresponds to the base of the broad ligament on either side. The incision is made at the junction of the cervical with the vaginal mucosa and not lower down, for the reason that the tissue surrounding the os is apt to be inelastic.

With the finger introduced into the posterior opening and shoved upward, the reflexion of the peritoneum forming the cul-de-sac of Douglas is encountered and usually is easily penetrated by the finger without incising it. This incision is enlarged by inserting the forefingers of both hands and doing blunt dissection laterally, carrying the uterosacral ligaments on the palmar surface of the fingers. At this stage a small pad is introduced into the posterior opening and attention is then given to the anterior surface.

The os is grasped on either side by bullet forceps and one blade of the scissors is introduced into the cervical canal; with the other blade anterior, an incision is made through the uterine tissue from the canal forward. Heavy traction forceps are then applied to either side of the divided tissue, and constant downward traction is made by the assistants. The incision is carried up to the fold of the peritoneum which is reflected on to the bladder, the traction forceps being progressively applied as the incision is carried upward.

At this stage, the finger as a rule can be made to penetrate the peritoneum close to the uterine tissue. If it dissects away from the uterus ahead of the finger, it can easily be grasped by a pair of long mouse tooth forceps and divided. The finger, when inserted into this opening, can easily be passed in a normal sized uterus to the fundus. It is then gently swept out to either side, carrying the bladder in front. After the bladder is dissected away, a trowel is inserted into the opening and the bladder is pressed forward toward the symphysis, thereby carrying the neck of the bladder and the ureters out of the field of operation. The ureter normally is about one inch from the cervix, but this trowel, inserted as it is, carries it even further away from the neck of the uterus and the uterine arteries, preventing damage to these organs. Anatomically the bladder extends out to the broad ligaments on either side.

The incision made through the anterior wall is carried up to the fundus. The fundus is seized on either side by strong traction forceps and delivered beneath the arch of the symphysis, bringing the annexa into view. If the annexa are diseased or adherent to the intestines, they can easily be separated, as is done through the abdomen, by the use of gauze sponges. The posterior pad is withdrawn and a large groove director inserted in the posterior opening, passing behind the uterus and out at the top of the fundus. This blade is held steadily in place by an assistant, and the operator then completes the bisection of the uterus with a long handled knife. Each half of the uterus is grasped firmly with heavy traction forceps and the hand is inserted into the pelvic cavity and the annexa are thoroughly explored. If they are adherent to the pelvic peritoneum or other adjacent viscera, the adhesions are gently broken up, freeing the annexa on both sides.

Half of the uterus is inserted into the pelvis, being firmly grasped with a pair of heavy forceps, while the other half with the fundus is drawn well down into the vagina. The thumb and forefinger of one hand are passed up through the opening behind the tube and ovary, and grasp the upper portion of the broad ligament; the ovarian artery can easily be felt pulsating. A hysterectomy clamp, with thumb and forefinger as a guide, is applied to the upper portion of the broad ligament, including the artery, from above downward, so that the heel of the clamp grasps the artery.

The intestines have already been well walled off by a thin abdominal pad. The upper portion of the broad ligament is then divided down to the point of the clamp and the second clamp is applied in such a way as to include the uterine vessel in its grasp as well as the portion of the undivided tissue at the base of the broad ligament. These clamps are steadied by an assistant, while the operator applies the same technic to the other side, removing the uterus and the annexa.

At this stage of the operation the pad is removed and the patient placed in the Trendelenburg position in order that the intestines and omentum may gravitate out of the field of operation, and a strip of gauze is inserted between the clamps on both sides and the vaginal mucosa, to protect that surface from contact with metal. Then the space between the clamps on either side is packed with recrystallized iodoform gauze, folded in such a manner that a yard in width is only about one inch thick; by means of lateral retractors this gauze is packed around the ends of the clamps to protect the intestines and omentum above and very snugly in a transverse plane holding the clamps down in the vagina.

A self retaining catheter is inserted into the bladder with instructions to have it opened every four hours. This is allowed to remain for four days, after which the patient voids her urine normally.

The clamps are left *in situ* for forty-eight hours, when they are removed. The gauze packing is changed on the sixth or seventh day, lighter packing being inserted; this packing is renewed every four or five days with two or three dressings, and the patient is put on a douche.

This operation has an added advantage in that there is never any fear of vaginal hernia owing to the fact that the base of the broad ligament becomes agglutinated to the vault of the vagina and serves as traction to keep the vagina of normal length. I have measured the vaginæ of many women before this operation, and two years after have found the length to be the same.

As to the aftereffect in the vault of the vagina, painful scars are out of the question inasmuch as the main nerve supply of these parts is cut off during the excision of the cervix.

The method described above suffices in all ordinary cases, but in those in which we have to deal with multiple fibroids the technic has to be modified because the size of the tumor is so geat that it cannot be delivered through the vagina without morcellation.

For morcellation, the technic of stripping the bladder up anteriorly and the posterior incision are the same as in the simple type of operation. But after having gained through the incision of the anterior wall to the midde zone of the uterus, V shaped sections are cut from either side of the incision and the sides are pulled in in such a manner as to draw the edges into the field If fibroid tumors of any size are encountered, they are seized either by heavy traction forceps or by a corkscrew instrument and, with the scissors curved on the flat and closed, they are manipulated from their bed, thereby reducing the size of the tumor.

In cases where the enlargement is more symmetrical, V shaped pieces are continuously cut away until the top of the fundus is reached; when this has been accomplished, the remainder of the uterus is pulled down underneath the arch, a curved director is passed behind, and the whole uterus divided into halves. The rest of the operation is then as previously described.

Case I. A case of this kind was that of Mrs. B. R., which I remember particularly because the chief symptom in uterine fibroid, hemorrhage, was lacking owing to the predominance of the pressure symptom. She was forty-seven years of age and there had been no sign of the menopause, which was of course significant. She was the mother of five children, the youngest four years of age, and had had four miscarriages since the birth of the last. For fifteen years she had backache, pain in the lower abdomen, and a leucorrheal discharge. Examination revealed a tumefaction in the right side, situated anteriorly, and the uterus was increased in size 300 per cent., being tilted backward. Operation was advised and vaginal hysterectomy was performed after the morcellation method. The patient made an uneventful recovery and, the abdominal pain and backache having disappeared, she was well satisfied at the result of the experience.

Another deviation is in cases of complete prolapse. Here the first part is carried on as before stated, but after the clamps have been applied, ligatures are inserted around the ovarian vessels behind the clamps and tied, while the assistant removes the clamps. The same method is applied to the uterine arteries, leaving the ends of the ligatures undivided. Kangaroo tendon is the preferable ligature material. The undivided ends of the ligatures about the ovarian vessels are threaded on a needle, and the needle is passed through the divided edges of the vaginal vault about one third of the distance up from either angle. The same process is gone through with the ligature about the uterine artery, outside of the ovarian vessels, so when these ligatures are tied into a ball in the vagina, the whole base of the broad ligament on either side is sutured into the vaginal vault. A small wick of iodoform gauze is placed in the middle, between the two ovarian ligatures which have been sutured in. This is left *in situ* for a period of three or four days, then removed, and iodoform packing is placed against the sutures, the idea being that the traction produced by suturing the base of the broad ligament on either side to the vaginal vault will be sufficient to keep the vagina patchless and the bladder in normal position. This is particularly applicable in the case of elderly women, as there is practically no shock and no risk beyond that of anesthesia in the elderly.

Case II. I recall the case of an old lady, seventy-two years of age, Mrs. H., who had borne several children and had grown grandchildren. She had passed the menopause at about the age of forty-five years. When she came to me for advice she had for fifteen years been a constant sufferer from complete prolapse. On examination I found that the uterus had so far descended that the erosion caused by friction was most severe, and for this reason walking and indeed moving about at all were seriously distressing. The uterus was almost entirely out of the body with both vaginal walls prolapsed, and the bladder was distended.

As is customary with me in these cases, the cervix was treated locally for some weeks until the erosion had nearly disappeared, the patient resting in bed. Then the operation described was done and the patient subsequently made an uneventful recovery. The results were most gratifying; three months after the operation, the patient called to express her appreciation; she was in perfect health, in the best of spirits, and was going about her household duties with an ease and comfort she had never expected to know again.

The results of vaginal hysterectomy in general have been all that I could wish. I do not mean to allege superiority of vaginal operation over abdominal, but wish only to show the results of cases where the vaginal method is applicable and preferable. In a series of cases comprising more than 300, there have been but three deaths; one from pneumonia, one from ether nephritis, and one from cerebral embolus. Not a single death could be traced directly to the operation itself; only to unfortunate accidents occurring with it.

117 West Seventy-ninth Street.

RADIUM.*

A Physical Curiosity and a Practical Remedy,

By Sinclair Tousey, A. M., M. D.,
New York.

It may interest my readers to learn of my first acquaintance with the x ray and radium, two of the agents through which I have been of the most service to my fellow men. The first time I ever saw the x ray was in a little side show where I paid a quarter and walked into a perfectly dark room. Presently I discovered that some one was trying to find

*Read at the meeting of The Audubon Medical Society, December 17, 1915.

my hand so as to hold it up before the fluoroscope and let me see the bones. One hand was busy protecting my watch and the other my pocketbook.

My introduction to radium took place when that too was an unknown quantity. We had heard of the wonderful light, so intense that a small quantity would blind every one in a large room; and of heat so intense that a certain small quantity would burn up the world.

Imagine my surprise when I found that we had to remain for some minutes in a completely darkened room in order to see the light at all. Then it was visible to only six of us who stood close to the table at which the demonstrator sat. We learned that the radium does not feel hot, but constantly generates in itself sufficient heat to remain at a temperature one degree higher than its environment. It is the same way with the electrical effects. They are visible to the naked eye, but delicate instruments and calculation are required to measure them.

We remember the wonderful dog who could talk. He could not talk wonderfully well, the wonder was that he could talk at all.

The marvellous thing about these slight, luminous, caloric, and electric effects of radium is that they are spontaneous. Ordinary substances give out heat which they have received from being near some hot body or from being subjected to chemical action, such as combustion, or from being subjected to friction or the passage of an electric current, or some other extraneous physical force.

Radium and other radioactive substances possess the unique property of originating force of various kinds through transformations in their own substance alone.

I have a spinthariscope which I bought a dozen years ago. It contains a tiny bit of radium in front of a fluorescent screen. Day and night for all these years thousands of particles have been thrown out from the radium every second. And as each particle strikes the fluorescent screen, that part of the screen becomes brilliantly illuminated for an instant. The whole effect is like a continuous display of fireworks. The radium and the fluorescent screen are enclosed in a dark tube, at the other end of which is a lens with adjustable focus. With a larger amount of radium we should see only a continuous general illumination of the screen and should miss the separate splashes of light due to the impact of individual particles.

On a larger scale a tube of radium for treating cancer and less serious troubles, is used by radiologists. To protect myself from its influence I carry it in a box wrapped in several thicknesses of x ray metal of the weight of the plumber's lead pipe. Inside is a silver carrying case and inside that an aluminum treatment tube. Finally we come to a sealed glass tube, within which we see the radium itself as a mass of crystalline powder about as large as the lead of an ordinary pencil and about two thirds of an inch long. This small quantity is worth several thousand dollars and is twice as much as the total amount used by one of the early German operators in a wonderful series of cures of uterine cancer and fibromyomata. These patients were treated in a hospital where all the radiation from the metal was acting upon the tissues of one patient after another for ten hours a day. If we darken the room we shall soon be able to see the faint glow from the radium itself. A much stronger light, almost strong enough to read by, is generated by a fluorescent substance such as zinc silicate held near radium. An interesting experiment is to enclose the radium in an opaque substance; a pocketbook will do. The luminosity of the radium itself is no longer seen, but there are invisible radiations like the x ray, which pass through the leather and brightly illuminate a piece of zinc silicate brought near it. These invisible rays which pass through opaque substances have the same fluorescent effect upon the diamond. A Spanish American physician who saw this property

FIG. 1.—Cicatricial contracture before radium treatment.

demonstrated in my dark room, spent the rest of the afternoon glancing at his diamond solitaire to see whether it had been permanently damaged.

The curative properties of such a tube of radium are applied in different ways. For certain cases an escharotic effect is produced which destroys all the tissues, healthy as well as abnormal, to any desired depth. Unlike the escharotic effect of chemical caustics and of the hot iron, there is no sensation at the time that the radium is applied. There is a period of incubation of some weeks before the effect becomes visible. After the part destroyed has come away the normal tissues are regenerated and the ab-

normal ones are usually found to have been permanently destroyed.

An example of this use of radium is to be seen in my own hands, which were badly affected by repeated exposure to the x ray. Cancer seemed inevitable, and while the different growths, x ray keratoses, had been removed with acids and a very great deal of suffering, they always returned. On November 10, 1914, I made an application of this identical tube of radium to a keratosis on the dorsum of the inter-

Fig. 2.—Cicatricial contracture, showing improvement after radium and operation.

phalangeal joint of the left ring finger. The growth had a translucent warty appearance with a black surface and was about half an inch in diameter and perhaps an eighth of an inch thick. It seemed to involve the entire thickness of tissue over the articulation. The surrounding skin was protected by x ray metal in a way of my own devising. A circle of double coated adhesive plaster was applied around the growth, and to the outer adhesive surface was applied a circle of x ray metal. The opening in the latter was large enough to expose the entire growth, but very little of the surrounding skin. Pieces of the same double coated adhesive plaster retained the radium tube in position, laid across the opening in the x ray metal. The application lasted thirty minutes. There was no sensation at the time or for many days afterward. The wartlike growth had been pared down almost to the bleeding point before the radium treatment and would ordinarily have sprung up in a few days, but it never did so. After a couple of weeks the joint took on a pink color without any feeling of inflammation. Thirty days after the application, the edges of the skin area looked white and loosened, and in a few minutes I had picked off the entire growth like a scab. This left a pink and tender but perfectly sound cutaneous surface in which there has never been a recurrence of the growth.

Next to be treated were two growths on the forefinger which had hollowed out the bone to some extent. They were permanently cured by a single application. Altogether about fifteen keratoses were treated and the remaining trivial one will be cured in the same way when I have time. The same kind of an effect is curative in cases of telangiectases or dilated bloodvessels disfiguring the skin for years after acute or chronic x ray dermatitis. This method is ideal for all kinds of warts.

The treatment of epithelioma is essentially the same. For example, the mother of a physician came to me with a deep ulcer in the ala of the nose, with indurated borders. A single application was followed by separation of the tissues, apparently in an unchanged condition, but leaving a healed and permanently cured surface beneath. Cancer of the lip would ordinarily be referred to the surgeon for excision; subsequently we should apply the x ray or radium by nondestructive methods to prevent recurrence.

In the case of a retired physician, eighty-two years of age, so grave an operation seemed undesirable, and I have treated the epithelioma of the lower lip with radium. The method has been the same as for the cases previously mentioned, but the effect upon a mucous surface is decidedly different. There is a molecular casting off of diseased tissue instead of a separation *en masse*. The old gentleman has returned for treatment every few months for the last year and a half. He is hale and hearty, and perhaps some time I shall be able to keep the radium in such successful contact with the growth on the inner surface of the lip as to prevent slight recurrences such as have been noted in the past.

The same destructive property of radium is made use of in the treatment of cancerous tumors of the neck, breast, or bones. In these cases it is often possible to introduce the radium tube through a puncture and allow it to exercise its destructive influence inside the cancerous mass.

The same application is made for vernal catarrh. Patients whom I have treated have had the upper eyelids covered on the inner surface with large masses of granulation tissue. These had resisted all effort at destruction by caustics and sprang up repeatedly after being cut away. Strong applications of radium, filtered only by the glass wall of

the tube, resulted in changing this granulation mass at first into white cicatricial tissue which looked like waterlogged skin. This finally changed into the normal lining membrane of the upper eyelid. During these applications it is my custom to protect the eyeball by a smooth metal shield hollowed so as to fit over the eyeball and inside the eyelids. The same destructive effect is made use of in cases of lupus erythematosus and also for nevus and other birthmarks.

To produce this effect in all the cases so far described, the beta rays are chiefly employed. The alpha rays are particles thrown out by the radium and have so little penetration that they will pass

FIG. 3.—Epithelioma of the lip, successfully treated with radium. Patient eighty-two years old; growth still remains healed two years after beginning treatment.

through scarcely half an inch of air and are practically all arrested by the thin glass wall of the tube. The alpha rays form about ninety per cent. of the original radiation, but are practically all excluded from use by this method of application.

The beta rays are also particles of matter, but have a much greater average penetration. Some are arrested by the glass walls of the tube, but most of them pass through and are the active agents in the cure of the lesions above described.

The gamma rays are vibrations very similar to the most penetrating x rays and readily pass through the glass. They form, however, an insignificant fraction of the radiation filtered by the glass tube alone, and are not instrumental in the cures.

Quite a different effect of radium is suited for the treatment of keloid and cicatricial contractures. The glass tube is surrounded by an aluminum treatment tube, which filters out about two thirds of the radiation which passes through the glass. This method applies practically none of the alpha rays or of the slightly penetrating beta, but all of the highly penetrating beta rays and all of the gamma rays. The radiation can be applied three times as long without unduly irritating the skin. No destruction takes place, but an alterative effect which causes disappearance of the fibrous tissue by a process of absorption. One such case in my practice was a keloid occurring in the cicatrix from appendicectomy. Another was the case of a hospital nurse who had extraordinary contractures crippling the hand after cellulitis with numerous extensive incisions in the hand and forearm. This latter case was referred to me by Dr. Forbes Hawkes, in the condition shown by the first picture. The hope was that treatment by radium and the ultraviolet ray would so affect the contractures and adhesions as to render operative treatment feasible. The motility was decidedly increased by my applications; then Doctor Hawkes performed an operation; then another course of my applications was made. The second picture shows the wonderful improvement, which has enabled the patient to become a stenographer and typewriter.

Still a third method of applying such a powerful tube of radium is by adding a lead filter through which pass only a small proportion of the most highly penetrating beta rays and the gamma rays. This lead filter may be from one twentieth to one quarter inch thick. The duration of each application varies from ninety minutes, as in a case of recurrent inoperable cancer of the pelvic viscera, to twenty-four hours for some cases of rheumatoid arthritis. The applications are made repeatedly and have accomplished a great deal in my practice.

The emanation from radium is an extraordinary substance. It is a gas, heavier than water. A bubble liberated in a bottle of water, but not yet dissolved, would sink to the bottom like a drop of quicksilver. The emanation charges any substance with radioactive properties, which, however, are lost when the radium emanation has become dissipated.

One way of applying it medically is to allow the patient to inhale air charged with it. An emanatorium may be a large room in which a number of patients are seated, the entire atmosphere being charged with the emanation from a very large amount of radium. This treatment by inhalation has given good results, especially in arterial and rheumatic cases.

A much more generally available method is by drinking water in which the emanation is dissolved. A single successful example may be interesting. A lady seventy years old had sciatica and a great deal of pain and lameness. This had persisted for years, in spite of medicine and massage. It was partially relieved when she came to me for treatment by high frequency currents applied from ultraviolet ray vacuum electrodes and by vibration. A good deal of pain remained, however, and about a year ago I started her on radium water. Within a few weeks, the pain was gone and there has never been a return. I have known of a number of cases with equally

prompt results and also of a number without perceptible benefit. The latter are perhaps cases due to infection, for instance, from a blind abscess of a tooth, and naturally medicine fails while the cause continues to pour poison into the system.

These remarks cover only a small part of the subject, but I thought perhaps a few personal experiences would be more acceptable than an encyclopedic article.

850 Seventh Avenue.

SYPHILITIC AORTIC DISEASE.

A Case with an Anomalous Electrocardiogram Suggesting Ventricular Asynchronism.

By G. W. McCaskey, M. D.,
Fort Wayne, Ind.

The introduction of the electrocardiograph and ink polygraph into clinical medicine has made possible the scientific study of many interesting cases of cardiac disease, which could heretofore only be carried on in well equipped institutions. Scientific medicine should be greatly benefited by the records of such cases, many of which occur far removed from large medical centres, to which such methods of investigation were formerly confined. The following case presents features which seem well worth study:

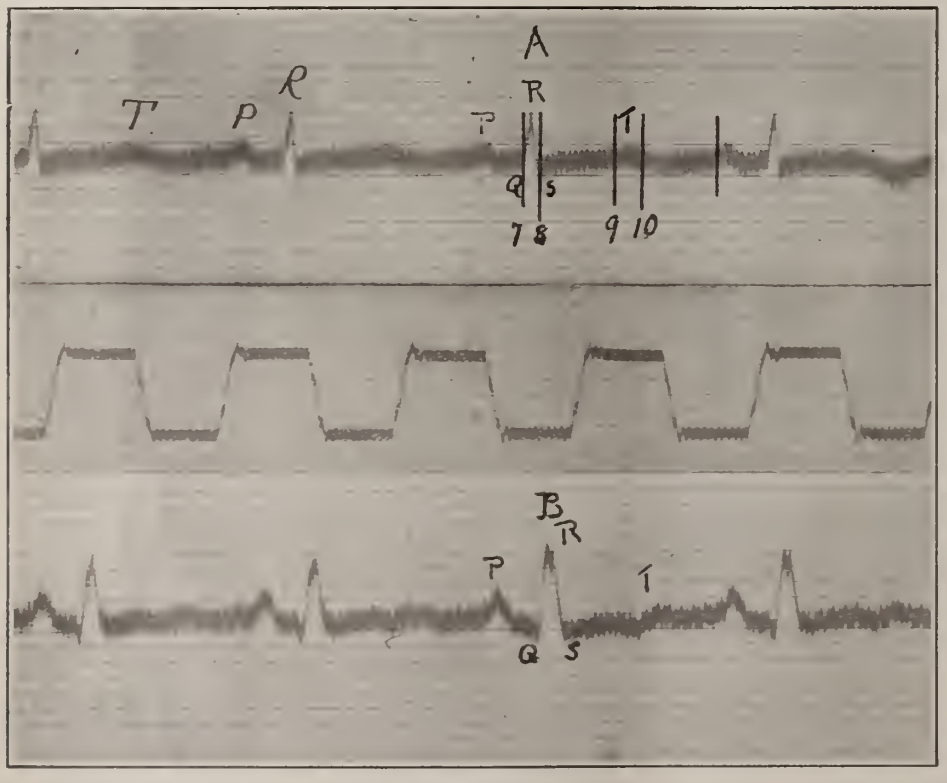

Fig. 1.—Electrocardiogram.

Case: Woman, aged thirty-three years, married, first seen in office, October 15, 1915. Complaint: Paroxysmal pain in upper left chest, and dyspnea. Family history: Father living, had arteriosclerosis and nephritis. Mother living and well. One brother killed by accident. No other brothers or sisters. Personal history: Had acute articular rheumatism when thirteen years of age. Eleven years later (nine years ago) began to have some symptoms of cardiac disorder. Recently these symptoms had grown much worse and consisted of sharp paroxysmal pain in upper half of chest on left side, caused mostly by exertion, though sometimes spontaneous. The attacks were severe, lasting an hour or longer, and associated with marked dyspnea.

Appetite and digestion poor. Menses regular and normal. Had three children living and well, the youngest two months old. One miscarriage followed first pregnancy. Unable to nurse any of her children.

Physical examination. Patient fairly well nourished. Thyroid palpable. Marked Corrigan and distinct capillary pulse. Temperature 99.2° F., pulse 100. Blood pressure (auscultatory method) systolic 170, diastolic 60 mm. Hg. Pulse pressure 110; at subsequent examination, systolic 160, diastolic 50. Heart: Left border three cm. to left of midclavicular line. Auscultation showed double aortic bruits, not very loud. No arrhythmia. Otherwise normal. No reduplication of either first or second sound could be detected at any time. Urine: Specific gravity 1.015, acid (40°), no albumin nor sugar. A few hyaline casts and leucocytes. Blood: Hgb eighty per cent., leucocytes 6,000. Blood, Wasserman +. Luetin doubtful.

The patient was placed upon mercury and iodides, the salvarsan preparations, with which the treatment would have started by preference, being available for only very grave cases at that time. She objected to the pain of intramuscular injections, which were followed by protiodide of mercury in doses as large as could be tolerated, about one quarter to one half grain three times a day. After about three months' treatment the symptoms are very much improved, although there are still occasional attacks. The physical signs are, of course, unchanged. Rest in bed was carried out as rigidly as possible.

On January 15, 1916, the Wassermann examination was negative. The aortic regurgitation, judged by the pulse pressure, should be extensive. The systolic pressure is nearly three times as great as the diastolic and the pulse pressure is 110. The capillary pulse is very marked. These points indicate rapid collapse of the peripheral arteries. Rather curiously this is not shown in the polygram.

There was no arrhythmia at the time of the first examination unless the disturbance of the R wave in the ventricular complex, to be shown later, is to be so considered. The sequence of successive cardiac cycles occurred in perfect time. The incidents of this wave can perhaps best be indicated and discussed by the aid of diagrams. Diagrams *a* and *b* (Fig. 2) are enlargements approximately to scale

(x6) of the R waves marked *a* and *b* in the first and second leads respectively. It so happened that these anomalous waves occurred at the time when lead II was taken. Very slight similar disturbances were shown in one or two of the R waves of lead III, but none in lead I. That they were due to a transient disturbance of heart action at the instant when lead II was taken is further indicated by their practical disappearance, only a bare occasional suggestion, in

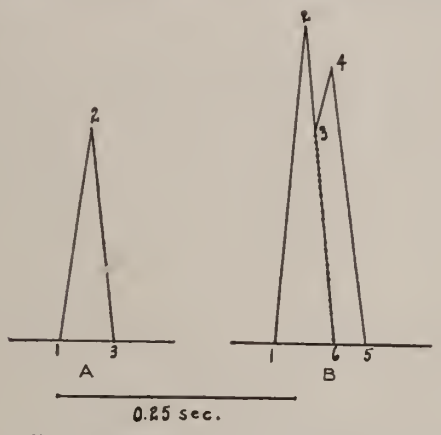

FIG. 2.—Diagrams of electrocardiograms.

an electrocardiogram taken November 11, 1915. They were not the result of any persistent perversion, functional or organic, manifested in lead II, in which the intercepted heart currents pass from the right arm to the left leg.

In studying these diagrams we find that the new electrical impulse referred to above occurred at the point designated 3 in Diagram *b*. Had this not occurred the R wave would have been normal or perhaps slightly prolonged, the down stroke of the wave reaching the base line at about 6, as indicated by the dotted line. The return of the deflected string to the rest position, being arrested at 3, the string is again deflected in the initial direction to 4, then dropping normally to the base line at 5. In these diagrams the time space on a horizontal line is indicated by the scale below which represents 0.25 second. It will thus be seen that from the beginning of the R wave at 1 to the beginning of the auxiliary wave at 3 is about 0.02 second.

The next most striking incident in this tracing is the greatly increased duration of the anomalous R wave as shown by the time from 1 to 5. This is about one twelfth of a second as compared with one twenty-fourth of a second in the normal wave as shown in Diagram 2—almost exactly twice as long.

Now what is the clinical and physiological significance of this bifurcated and prolonged R wave? The R wave is the principal or at least the most conspicuous event in what is called the ventricular complex, which includes the waves arbitrarily designated Q, R, S, and T. In other words, all the events of the ventricular systole, including the initial electrical phenomena, occupy the time between the ordinates marked 7 to 10 in the ventricular complex designated *a* in lead I. Q and S are often inconspicuous or absent. The R wave is due to an electrical current caused by a relative negativity of the base of the heart, immediately preceding the actual contraction of the ventricular muscle, which begins almost exactly as the R wave ends.

It will thus be seen that the bifurcation of the R waves occurs during a precontractional systolic event, which is, however, probably just as essentially a part of the ventricular systole as the mechanical movements of contraction. Does it indicate an asynchronism of the ventricles? It cannot be due to successive reversals of electrical conditions in the same musculature caused by successive contractions. Such phenomena do not follow each other so rapidly as in periods of 0.02 second.

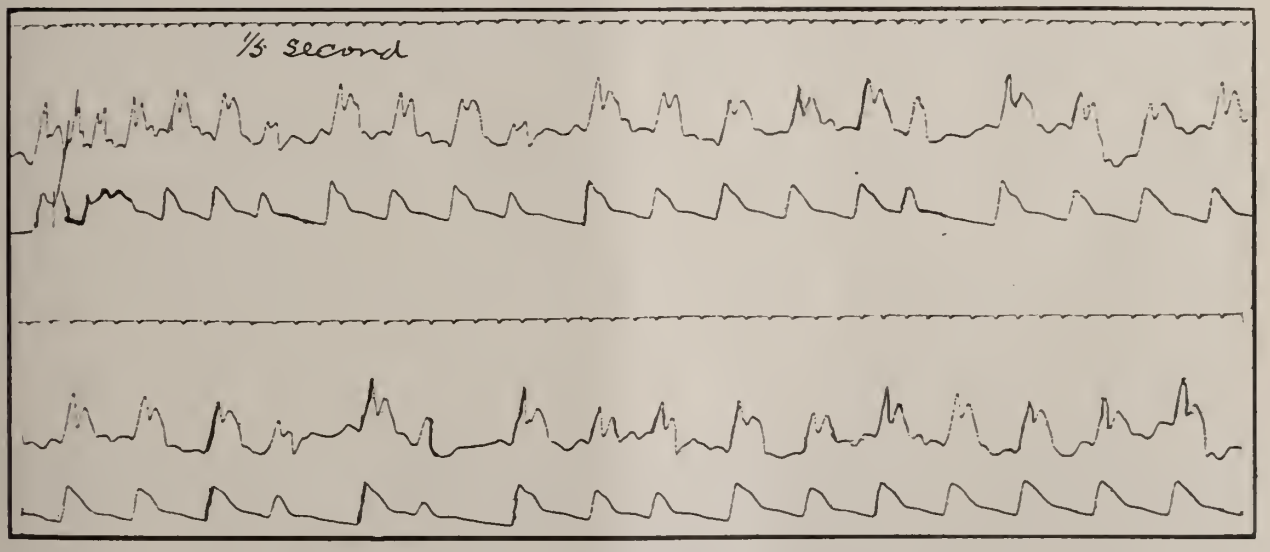

FIG. 3.—Polygram.

It may, I think, be confidently assumed that the secondary R wave is caused by electrical changes initiated in a group of muscles entirely distinct from those responsible for the primary wave. That the two ventricles might constitute the two muscular areas indicated seems plausible. That the ven-

tricles may act asynchronously has been proved experimentally and assumed clinically by competent investigators. So far as this particular form of electrocardiogram is concerned, I am unable to find anything like it in the clinical records of the literature at hand. The only similar tracings that I can find were produced experimentally by Lewis (*Mechanism of the Heart Beat,* 1911), and resulted from heart cycles originating in the ventricle by abnormal stimulation below the auricle. That the anomalous R wave in this case was not produced in this way is proved by the fact that the contractions are of the physiological supraventricular type, originating in or near the "pace maker." In most of Lewis's electrocardiograms above referred to, the auricular contraction (P wave) follows the ventricular. In this case the P wave precedes the R wave by a perfectly normal time, thus establishing not only a normal sequence of the cardiac events, but a normal conduction time between auricle and ventricle.

I do not think that the electrocardiographic evidence in this case proves ventricular asynchronism. The most that can be said is that from some cause, perhaps a lesion of the branches of the a. v. bundle, irregular contraction of large muscular masses occurred.

It so happens that the polygram taken at another time recorded arrhythmias which were entirely absent at the time when the electrocardiogram was taken. These arrhythmias occurred in parts of the polygrams only, one advantage of which over the electrocardiogram is that the ink tracing can be continued for any length of time, thus enabling the clinician to secure a graphic tracing for study over a long period of time. The easy portability of the polygraph is another important point in its favor.

The irregularities of heart action shown in the polygram are apparently all of sinus origin. The ventricle responds to the auricle regularly, although the latter is not regular. There is a considerable variation in the height of the apices of the radial tracings, which is at times suggestive of the very serious condition known as pulsus alternans. In many if not all of the small arteriograms, however, the corresponding venous wave is abnormal, so that the ventricle was perhaps not adequately filled. This would, of course, diminish the volume of blood distributed to the peripheral arteries, and limit the expansion of the radial artery upon which the characteristics of the tracings depend.

The diagnosis is undoubtedly syphilis of the heart and aorta, with evident involvement of the aortic valves. It is true that there is a history of articular rheumatism which has to be taken into account as a possible etiological factor. The mitral valves, however, which are the site of predilection of "rheumatic" infections of the heart, were not involved. The only anatomical lesions clinically demonstrable were in the aortic area. The fact that about seventy-five per cent. of all cases of aortic disease occurring in early adult life are due to syphilis, coupled with a positive Wassermann, and steady improvement under antisyphilitic treatment, clinches the diagnosis. The prognosis for a relative recovery seems good.

The interpretation of the anomalous electrocardiogram is admittedly doubtful, but, taken in connection with the arrhythmia demonstrated by the polygram, we may reasonably infer a rather widespread treponemal infection of the heart, by no means limited to the aortic zone. That such a condition might be expected in cardiac syphilis is indicated by the work of Warthin, from which it would appear not only that the heart is a site of predilection for the treponemata, but that they can in such cases usually be found widely distributed throughout the tissues of that organ. If Warthin's work is to be credited, then treponemal infection of the auricular wall, of the branches of the bundle of His, and other widely separated structures, can almost be fairly assumed, whether it produces active clinical manifestations or not.

Physicians' Defense Building.

TRANSMISSIBLE DISEASES IN WAR.

By P. W. Huntington, M. D.,
New York,
Captain, Medical Corps, United States Army.

There are no diseases peculiar to the soldier, but there are several classes of diseases, embracing many separate pathological entities, to which soldiers, by the nature of their occupation and surroundings, are particularly susceptible, especially in time of war.

It is easily understood that sanitary conditions in war are necessarily much different from those of peace; that is, that military exigency and advantage take precedence over sanitary measures.

When sanitation is necessarily violated for reasons of military urgency, however, the commander should be aware of the fact and should be able and ready to pay the inevitable price in the future reduction of efficiency. It is well known that in nearly all past wars preventable disease has killed more men than have perished from wounds. In the Civil War there were killed in battle and died of wounds 93,969; died of disease, 186,216. In the Spanish-American War deaths from battle, 293; from disease, 3,681. These examples might be multiplied almost indefinitely and, in all wars, the deaths from disease are caused by preventable diseases in by far the greatest number of cases, and are due to ignorance or misapplication of the laws of hygiene.

There are four classes of diseases to which soldiers are particularly liable, namely, intestinal, respiratory, renal, and venereal. As it would be impossible within the scope of a paper such as this to discuss all the diseases in these classes, we shall consider first, and as the type disease of the class of intestinal diseases, typhoid fever.

TYPHOID FEVER.

Colonel Kean has truly said that "typhoid fever is today, on account of its wide dissemination, the persistent vitality of the infecting organism, the duration and severity of its attack, and its large death rate the most formidable infectious disease with which we have to contend in military life." In garrisons it is comparatively easy to control typhoid,

but in camps the situation is very different on account of the difficulty of disposing of human excreta, lack of facilities for bathing, and constantly renewed contact with articles in common use. As typhoid is endemic in the United States, it will hardly be possible to mobilize any unit without including an incubating case, a convalescent, or a carrier. We may look on such cases as inevitable, but should be duly on our guard to learn of them at the earliest possible moment to prevent further cases; in other words, to prevent this preventable disease. We must be particularly careful not to overlook the mild or otherwise atypical cases, as our experience in the Spanish-American War showed that such were frequently the starting point of company epidemics. We do not here need to concern ourselves with the symptomatology, pathology, or treatment of typhoid, but chiefly with its prevention. In order to accomplish this we must apply the rules of hygiene that are applicable to all intestinal diseases caused by a living microorganism which is introduced with the food or drink. These are: 1. The deposit of the excreta in proper receptacles under proper conditions; 2, the provision of a food and a water supply that is uncontaminated; 3, the preaching and practice of cleanliness; 4, the isolation of the sick, and, 5, the prevention of the fly. In addition to these general measures we have another which is especially applicable to typhoid, namely, the antityphoid vaccine.

To furnish an uncontaminated water supply to a command in the field is a much more difficult problem than might be supposed. To this end the following rules may be a help: 1. In all cases of doubt, have the drinking water made safe by boiling, by use of the Darnall filter, or the Lyster hypochlorite bag; 2, regard all surface water as doubtful; 3, water from deep (artesian) wells is usually safe. The care of the food supply naturally includes measures for the selection and training of cooks, provision and preparation of the food under proper conditions and its protection from contamination until consumed—this latter to include screening of kitchens and mess tents whenever necessary. The measures in regard to excreta include providing proper pits, latrines, as they are called, with fly proof covers, for the reception of feces and urine, and, also providing water nearby for cleansing of hands. The details of latrines, incinerators, baths, and many other sanitary measures and appliances will be taken up in a later paper on the subject of camp sanitation.

The necessity for the isolation of the sick is at once understood. The prevention of the fly is a measure of some difficulty, especially in camps of mounted troops. The necessary measures include careful sanitation of picket lines, the disposal of manure by burying, burning or drying, and careful attention to the surrounding civilian settlements which are often breeding places of myriads of these pests. Fly traps of proper construction and properly baited can produce a noticeable diminution in the number of flies. Last and most important, all these measures must be supplemented by the vaccination of the entire army, and the surrounding civil population if it is thought necessary. It must be remembered that the military medical officer will always in war time be the final authority as to the sanitation of areas within the zone of operations and also in the vicinity of camps of mobilization.

The antityphoid vaccine in use in the United States army is a whole killed culture of the Rawlings strain obtained originally from the spleen of a fatal case in England. This strain still retains its toxicity and a considerable degree of its virulence. Its efficiency in the vaccine depends on its toxicity. The vaccine is prepared in the laboratory of the Army Medical School in Washington, D. C., and is required to be given to every enlisted man and officer in the army. Three doses (500 million units—1,000 million units—1.000 million units) are given, at ten day intervals. That its use has been attended by satisfactory results is shown by the fact that whereas before 1910 there were in the army, annually, in a strength of about 86,000 men, about 300 cases, since 1910 there have been, in five years, thirty-two cases. During that time there have been no great advances in general or military sanitation to account for this tremendous decrease in typhoid incidence. It should be remembered that the soldiers at almost all stations mix freely with the civilian population, and that several times in the past five year camps have been near towns in which typhoid was prevalent, as at San Antonio, Texas, in 1911 and 1912. The immunity probably lasts on an average for two and a half to three years. The vaccine rapidly loses its toxicity and therefore its efficiency after four months is considerably lessened and after eight months it is probably quite inert.

In the European armies a polyvalent vaccine containing Bacillus typhosus, Bacillus paratyphosus A, Bacillus paratyphosus B, and Streptococcus choleræ asiaticæ is being used with good results.

PNEUMONIA.

Pneumonia is, of course, a disease of war time on account of the conditions of hardship and exposure incident to campaigns, especially in such trench warfare as is now being waged in France. Its prevention depends on the avoidance of those factors in so far as possible and the prohibition of the use of alcohol by the troops. In regard to its treatment nothing new can be said except that, among soldiers, the death rate, usually, will be low, as they are a selected set of men of favorable age with presumably healthy hearts.

BRIGHT'S DISEASE.

Acute Bright's disease has been one of the medical problems of the present war that has caused and is still causing much discussion. There have been a large number of acute cases among the men from the trenches who, when brought back to the base hospitals, were found to have partial or complete suppression, edema, and all of the usual symptoms of acute Bright's disease, which was thought to have been produced by cold and other hardships, until it was found that several of the hospital orderlies and others at the base, who had not been exposed to these hardships, were manifesting the same symptoms. It is now an unsettled question whether

this particular type of Bright's disease is not due to some specific infectious cause. The cases have nearly all ended in rapid recovery with rest and the usual attention to diet and drink.

VENEREAL DISEASES.

Venereal diseases have for years been, at least in our army, the greatest and most important cause of constant ineffectiveness, being, in our army of about 86,000, the cause of a constant loss of the services of the equivalent of about a regiment of men. Compared with other diseases they become of less importance in war time, but in the past this has not been due to any decrease in the incidence of venereal diseases, but to the fact that other diseases are more common.

Field Service Regulations provide for a physical examination of the men of a command about to take the field, and, at that time, the medical officers should make an earnest effort to detect all cases, as infected men would quickly break down under the terrific strains incident to modern warfare. The admission rate for venereal diseases has been higher in the United States army than that of any of the European armies, but, as human nature is much the same in all countries, I am inclined to think that the difference is much more one of records than of facts.

In regard to the treatment of these diseases, the military surgeon has no methods that are not available to the whole profession, but we do have the advantage of having our patients under military control and of being able to follow them up for years if necessary, at least as long as they remain in the military service.

In regard to prophylaxis, one of the most efficient means that we have at hand was provided by Congress when it enacted that no man should receive pay for any time lost from duty by reason of alcoholism or disease, the result of immoral habits. Venereal morbidity in our army has been much reduced since 1912 as the result of orders which initiated the system of personal prophylaxis now in use. In general it is as follows: Each man who, while away from his barracks, has exposed himself to possible venereal infection, is required, on returning to the post, to proceed at once to the hospital, where a room is set apart and an attendant is always on duty to see that prophylaxis is properly carried out. This consists of a preliminary cleansing with soap and water, then an injection of two per cent. protargol solution, followed by a thorough and painstaking inunction of all the genital parts with thirty per cent. calomel ointment.

I think that nearly all medical officers feel assured that this procedure will, if applied within three hours after exposure, prevent practically all cases of venereal infection. A card record is made of the prophylactic treatment at the time, showing the hours of exposure and of treatment. To prevent concealment of cases and to discover unsuspected cases, all enlisted men, with the exception of married men of good character, receive a careful physical examination twice a month. If any man conceals a case of venereal disease, or, having a case, fails when exposed to take the prophylactic treatment, he may be and usually is brought before a court martial for trial and punishment.

In my opinion a collapsible tube containing small quantities of the agents necessary for this prophylactic which could be issued to the men without cost, would protect nearly all of the remaining infections, as experience has shown that they occur now in men who are on pass for twenty-four hours or more, or in chronic alcoholics, or in men who for some reason or other do not receive the prophylactic within a sufficiently short time after exposure.

Further important measures of prophylaxis include instruction in the benefits of continence and the dangers and prevalence of venereal diseases, and, last and not least, in providing the soldier with some employment for his mind and hands when off duty, for it is still true that idleness fosters vice. In time of war all loose and lewd women should be promptly expelled from the zone of military operations and in and near garrison towns the prostitutes and shop girls should be kept under careful oversight.

39 Whitehall Street.

SYNCOPE IMMEDIATELY AFTER THE ADMINISTRATION OF DIARSENOL.

By Sylvan H. Likes, M. D.,
Baltimore;
And Herbert Schoenrich, M. D.,
Baltimore.

During the past three months we have had occasion to administer numerous intravenous injections of a preparation made in Canada and which we understand the manufacturers hold to be identical with the German salvarsan, and to which they have given the name diarsenol. This preparation is marketed in glass ampoules, consists of a yellow powder in appearance similar to the German product, though the contents of some of the ampoules were of a darker shade of yellow. The powder seems to dissolve somewhat less readily than salvarsan, requires a greater degree of heat for its complete solution, and gives off a rather strong garlicky, disagreeable odor. The precipitate which forms after the addition of the alkali is darker, which is also at times the case with the solution when ready for administration. In mixing the powder, we noticed that the bulk in different ampoules containing the same dose varied; this fact was made more evident when placing a number of ampoules side by side in a rack, even though we made allowances for the possible difference in the diameter of the ampoule.

The therapeutical efficacy of the drug did not seem to differ materially from that of salvarsan. Initial lesions healed within ten days. Secondary lesions, particularly macular syphilides, yielded readily. Encouraging results were also observed in cases presenting some of the other phases of syphilis. The Wassermann test, which in our work is made not only as a means of diagnosis but with which every case is carefully followed up, was influenced favorably by repeated doses, and occasionally by even a single injection of diarsenol.

The main point of interest is the peculiar reaction which in some cases has followed the administration of diarsenol. On the whole, the reaction we may expect does not seem to differ very materially from that of salvarsan, although it was observed in a greater percentage of our cases, and when present came on earlier, was more severe in character, and in three cases to be hereafter mentioned, indeed alarming. It is with a certain degree of amusement when we think back to our early experience with salvarsan, when we took all the prescribed precautions for giving absolute rest to the patient for several days following the treatment, how the first few patients were carried from the operating table to a room specially fitted for this purpose where they were kept for three days, the temperature being taken every four hours and the urine examined each day. Following this, patients went unassisted to the room and were kept there for one day. Not seeing any alarming aftereffects, we have since then advised our patients either to rest at our office for six to eight hours, or to go home immediately and rest there for a similar length of time. We have administered several thousand intravenous injections of salvarsan in the past five years, and while reactions followed in possibly sixty per cent. of our cases, the symptoms were fortunately never alarming in character and consisted largely of headache, rigors, and fever; the more severe reactions being accompanied by nausea and vomiting. In only one case was the reaction sufficient to cause anxiety. In this instance there was a suppression of urine for twenty-four hours, due to a nephritis evidenced by albumin and casts in the urine. This nephritis lasted for several days, after which the urine became normal and the patient experienced no further trouble. Several patients, although against our advice, did not take the prescribed rest and immediately went on with their customary duties and nevertheless suffered no ill aftereffects. Furthermore, reactions seldom came on before the expiration of one hour; they usually appeared during the second hour, but seldom later.

Prompted by the fact that after five years' experience with salvarsan with absolutely no alarming symptoms other than the exceptions mentioned, we naturally followed the same procedure when administering diarsenol. The technic employed in the preparation of the fluid was that recommended by the manufacturers. Our experience with the drug was at first practically the same as with salvarsan, until we administered the eighteenth injection.

THE EIGHTEENTH INJECTION.

The patient had already received five intravenous injections of salvarsan. On January 25th he received 0.6 diarsenol with practically no reaction. Two weeks subsequent to his first diarsenol injection, he had a second dose of 0.6 diarsenol. Hardly had we completed its administration, when the patient went into a profound syncope with profuse sweating and extreme pallor. The wrist pulse was not palpable. Fortunately, this attack was of only short duration, as the man responded rapidly to the inhalation of amyl nitrite and hypodermic injections of strychnine. He was able to go home in an hour's time. On March 4th he received 0.4 diarsenol with no subsequent reaction.

THE TWENTY-SECOND INJECTION.

This patient had on a previous occasion received 0.6 salvarsan, followed in an hour by a fairly marked reaction. On February 21st he had 0.6 diarsenol injection. Immediately after the treatment and while the patient was still in the recumbent posture on the operating table, he was seized with intense nausea and violent vomiting, and became extremely exhausted. There was very slight syncope, but no loss of consciousness. The radial pulse was rapid and respiration shallow and rapid. He was kept in the recumbent position for over an hour, after which he regained his strength and was later able to proceed to his home.

THE FIFTY-THIRD INJECTION.

This case is of interest, first from the viewpoint of salvarsan, in that the patient showed unusual resistance to antisyphilitic treatment, in spite of the fact that the diagnosis was made early; and, second, from the viewpoint of diarsenol on account of the rather alarming reaction.

He first consulted us, September 24, 1912, presenting a sore on his penis of only a few days' duration, which was recognized as luetic by the aid of the dark field condenser. Within twenty-four hours of the diagnosis he received 0.6 salvarsan, which caused the initial lesion to disappear in ten days. Subsequently he received twelve more injections of salvarsan and this treatment was reinforced with mercury and potassium iodide. His Wassermann test taken on frequent occasions showed a varying degree of hemolysis, the last test, February 17, 1916, still showed one plus. This failure to obtain a negative Wassermann in cases in which the diagnosis was early established, viz., within a few days of the appearance of the initial lesion and energetically treated, is contrary to our experience.

The fact that his last Wassermann test was still positive, prompted us to administer 0.6 diarsenol. This was his first injection of the new product, and was given on March 8th. Within two minutes following its administration this patient went into a profound syncope. First, his face became deathly pale, then cyanosed, profuse sweating ensued, the wrist pulse was not palpable and only the first sound of heart could be heard. Respirations were not perceptible; there was a loss of consciousness and his pupils were widely dilated. He had inhalations of amyl nitrite and strychnine hypodermically, and within a few minutes he showed signs of returning consciousness, and then became intensely nauseated and vomited profusely. The wrist pulse and heart sounds soon became normal; he was kept under close observation for three hours, at the end of which time he was in fairly good shape and able to go home.

In no case observed so far has there been any evidence of kidney irritation nor change in the urinary secretion.

We cite these three cases because they contrast with the numerous others in which salvarsan, diarsenol, or both, have been given, and, strange to say,

it was only with the more recent injections that we encountered trouble. From the fact that diarsenol on previous occasions and subsequently had been given without reaction other than might be expected to follow salvarsan, and that alarming reactions occurred in individuals who already had diarsenol treatments without untoward symptoms, we should infer that this unusual reaction is not due to suceptibility on the part of the patient, but rather to some possible variation in the drug itself.

It will be our plan in the future until we have learned more concerning the exact cause of the peculiar reaction, to give a somewhat smaller dose and have the patient maintain the recumbent posture for at least fifteen minutes. From our limited experience, we feel that if there is no evidence of syncope within that time it probably will not occur.

1134 Linden Avenue.

CHRONIC INTERSTITIAL NEPHRITIS,

An Apparently Hopeless Case, Benefited by Treatment with the Emanations of Radium and Thorium.

By Francis E. Park, M. D.,
Stoneham, Mass.

It seems strange that at this late day, when for several years in leading centres of Europe, notably Berlin, Vienna and Budapest, there have been in successful operation institutions where the internal diseases are being treated with emanations of radium and thorium with wonderful success, that apparently scant notice and interest is taken in the results by the medical profession in this country. It is in the hope of awakening interest and stimulating research work among our men that this case is reported. It is but one of many, but I think will be more striking if related alone.

In the fall of 1914 I was called in consultation to see a lady in a neighboring town. Her physician told me that she had been in poor health for several years, getting progressively worse. The preceding year she had spent in Germany under the care of a celebrated practitioner, but had returned weaker than when she went. At that time she had come under his care, and he had found well advanced lesions of the kidneys and arterial system. There had followed the usual sequence in such cases, and in the summer of 1914 she had been compelled to take to her bed. It was decided at a consultation that there was practically nothing more to be done, and from that time until I saw her, the following October, she had been confined to bed a large part of the time.

Case. On examination, I found a woman of sixty-two years, fairly well nourished; color poor; tongue coated; slight degree of anarsarca present. She was very weak and unable to assist herself. On examining the heart I found a mitral murmur which her physician assured me had developed within a few months and had grown steadily louder. The organ was beating irregularly, 120 to the minute, and the blood pressure, systolic, was 240 mm. Hg. The urine was pale, specific gravity 1.010, with slight trace of albumin. Digestion was impaired, there being much fermentation, and she had a great deal of gas. She complained very much of pressure in the head and singing sounds in the ears.

This history of a progressive decline under good care and treatment, coupled with the very bad general condition, made me feel dubious as to the result, but as a last resort the family wished to try radium treatment and she was accordingly removed to Stoneham and placed under my care. The treatment that was instituted tended to keep a constant degree of radioactivity present in all of the body tissues, while the diet was carefully worked out so as to avoid fermentation as much as possible. All through the early weeks of the treatment it was necessary to use the various forms of pepsin and the usual mild stomach remedies such as tincture of nux vomica, bismuth, sodium bicarbonate, etc. Apart from this, which was along the same lines as formerly, the treatment was entirely with the emanations. These were given both in drinking water and intravenously. There was also some radioactive effect derived from a pad which she wore constantly over her heart. During the latter part of the treatment she was able to go into a radiotorium and inhale the air which contained ten Maché units to the litre. She also was given, through the first half of her stay, thirty c. c. of radioactive plasma (Quinton) daily.

After the first week she began to show signs of improvement. Up to that time she was so weak as to be unable to feed herself. On the tenth day she sat up on the side of the bed for a few minutes. From that time on, the improvement was steady, though very slow. The time of sitting up was lengthened and more frequent intervals were observed. The appetite began to come, and there was a steady change in the urine. At the end of eight weeks she was eating a variety of things and walking about the room. The heart action was markedly altered, the rate dropping toward normal and the murmur becoming indistinct.

By January the urine was practically normal, also the heart, except when under some excitement, and she began walking outdoors a little. The feeling of pressure and the noises in the head began to diminish. Shortly afterward she was greatly pleased to discover that she could hear her clock tick from its accustomed place in the room, something she assured me had not happened for several years. By February she was walking every morning, half a mile on the sidewalk in front of the sanatorium, and her pulse was constant at 72, while the murmur was not to be heard. She was eating well and was the picture of health. She discontinued treatment at this time and returned to her home. The subsequent history up to the present time, a year later, is that of improvement. She is back in her home life, outdoors every day and, as she recently expressed herself to me, "gaining all the time."

Now we have here the history of a case that seems, judged by our old standards, impossible, yet it is strictly as reported, and enough careful observers saw the case to put the diagnosis beyond a peradventure. She had had the best of care from the onset of her disease, and in spite of it had followed the inevitable course, then, at the eleventh hour, was subjected to the influence of radium and thorium, and at once swung about and crept steadily back to a condition of comparative good health, and is

still tending to improve, a year after ceasing treatment. As I look back and compare the case with many others that I have personally seen that were just as wonderful and some of them of widely diverse conditions, I feel sure that in the radioactive emanations there exists a power such as we have never known before, that stimulates the vitality of the individual protoplasmic cells and assists them to regain their function.

So far my work with the emanations has been limited to very chronic types of disease. This is to be expected, for on the same principle that a drowning man grasps at a straw, so these hopeless patients who have tried everything in vain reach out for a possible help in radium and in the great majority of cases find it. The point I wish to make is this: If radium and thorium emanations have the power to help advanced cases of disease—and I think we must admit that enough evidence has been accumulated from the great number of cases reported by various observers—then how much more beneficial will they be if used in the early stages when the functions are first becoming deranged. Judging from a two years' large experience in this field, I venture to predict that the day will come when it will be a customary thing as middle age is reached, regularly to take a course of radium treatment in order to revive and stimulate the functions of the whole body and put back by appreciable years the inevitable decline which we call old age.

A TRUSTWORTHY NONPOISONOUS ANTISEPTIC.

By William M. Gregory, M. D.,
Berea, Ohio.

When Doctor Crile, of Cleveland, returned from his tour of duty in the European military hospitals he remarked: "Modern antiseptic treatment has totally broken down in its application to military surgery in Europe." We hear from time to time of fatal accidents resulting from the careless use of mercury bichloride.

It is a good time to remind the entire medical profession, and especially the surgical end of it, that calendula will kill all pus germs. As the drug may not be familiar to some, I will say that I refer to the nonalcoholic fluid extract of calendula, which is Calendula officinalis, the common or garden marigold. Perhaps fifteen years ago I read in some medical journal that "a good extract of calendula will absolutely prevent the formation of pus in all contused and lacerated wounds, no matter how dirty, unclean, and far from aseptic they may be." I considered this statement probably exaggerated, but tried the remedy, and found that it made good in every instance. I have done a good deal of accident and emergency surgery, and have had some exceedingly filthy wounds to treat, caused by railroad and stone quarry accidents, contaminated by coal dust, machine oil, and dirty clothing, and not one of them has ever produced a drop of pus when dressed with a good extract of calendula.

Extensive burns are pretty sure to become contaminated from burned dirty clothing and other causes, and if dressed with linseed oil and lime water, will be covered with foul yellow pus in about two days. If dressed with calendula and saturated solution of boric acid, the burns will remain perfectly clean and sterile till healing is complete. Beside its antiseptic qualities, calendula alleviates the pain of burns better than any other remedy ever discovered. It is so much better than dilute picric acid that any one who has used it for burns will never care to use the acid. I wish to make my meaning perfectly clear, I do not mean that it has sometimes, or occasionally prevented pus formation in dirty wounds, but that it has absolutely inhibited the formation of pus in every wound that I have ever dressed with it.

If you ask me how it does this, I have to say frankly that I do not know, as chemistry can tell us nothing about it that I know of. It is a nonpoisonous plant, often used internally, and is the best remedy I have ever found for a certain very acute and inflammatory type of gastric catarrh.

Have any of the readers of the Journal ever been called to treat a badly bruised or wrenched knee joint with a violent acute synovitis rapidly setting in? If they have, they know what wreck and ruin is likely to take place unless the doctor is both energetic and skillful. In a case like this, two ounces of concentrated extract of calendula, six drams of lead acetate, to one pint of hot water, applied on compresses of absorbent cotton, will work a wonderful cure. The lotion must be applied very hot, and the compresses must be changed before they get cold. This treatment, faithfully end energetically followed up for two or three days and nights, will positively prevent effusion, suppuration, and the wrecked and ankylosed knee joints that I used to see in my hospital days. This treatment is equally good for a badly sprained ankle.

I wish especially to warn the profession to get a reliable preparation of this remedy, as there is much on the market that is almost worthless. The reliable fluid extract is so concentrated that it is almost of the consistence of syrup. In that form of erysipelas in which a light red surface is interspersed with numerous pustules, and which is most certainly a mixed infection, calendula, lead acetate, and saturated solution of boric acid will effect a prompt cure.

An exceedingly efficient treatment for very bad cases of leucorrhea contains equal parts of nonalcoholic calendula, nonalcoholic hydrastis, and glycerin. This prescription can be used on tampons, or with hot water as a medicated douche. Where patients object to the present very high price of hydrastis, the calendula, boric acid, and glycerin can be used with great success.

General knowledge of the power of calendula as a germicide, and its general use in hospitals and surgeries, would prevent thousands of cases of infection and suppuration every year. It is no new or experimental remedy. It has been thoroughly tried out. It has stood the test of years, and it is absolutely sure death to all pus germs whatsoever. But it must be the right calendula. Many a man, not knowing good from bad, has tried some poor preparation of the drug, got no good results, and concluded that the claims made for it were false.

Lectures and Addresses.

A PRESIDENTIAL ADDRESS.*

By Albert C. Geyser, M. D.,
New York.
Professor of Physiological Therapy, Fordham University Medical College.

Members and Guests of the New York Society for the Promotion of Physical Therapy:

It is my privilege and pleasure to bring to your notice the scope of our aim, the goal of our endeavor. This society has been guarded in the selection of its members for several reasons. In the first place, membership was limited to professors and clinical instructors and to those of the medical profession who practically specialized in this field of therapeutics.

The reason for this was that whatever emanated from the members was expected to be based upon the sound reasoning that is born of real practical, everyday experience. Long experience has taught that however much we may owe to the great minds that evolved basic generalizations and hypotheses, real progress in science ultimately rests on the establishment of facts. Our reasoning faculties by themselves are unable to cope with the complexity in the physical world, and are sure to stray from reality unless they are continually guided by observation and experience. Nature always proves to be less complex and ever so much more simple in her operations than would seem to be true to the theoretical considerations of the closest philosopher. In the minds of those who formed this society was the dominant thought that whatever emanated from this society must be the acme of science built upon the corner stone of truth.

This society sees before it a duty to itself, a duty to physical therapeutics, and a duty to medical science. The duty that it owes to itself is to be ever guarded in the selection of its members. Science, experience, and truth are the pass words that lead to its sanctum sanctorum, and without adherence to the full meaning of these words no man should be able to enjoy the pleasure and privilege of its membership. Quality not quantity is our aim.

This society has taken upon itself the endeavor to place physical therapy upon the high pinnacle that it so justly deserves. It will relentlessly wage war by every lawful means as its disposal to uproot any and all quackery practised by the lay pretender.

This society does not subscribe to the altogether too prevalent idea that *"to practise physical therapeutics is not to practise medicine."* On the contrary, it firmly believes that only a graduate in medicine is capable of appreciating the actions and reactions which take place almost immediately under his eyes the moment such means as electrotherapy, hydrotherapy, thermotherapy, psychotherapy, phototherapy, etc., are applied to the living body.

It was only a short time ago that the practitioner was compelled to abandon the idea that electrotherapy was useful only in diseases of the nervous system. Because the electric current, especially the faradic or the galvanic, was able to furnish such unerring data in the diagnosis of central and peripheral nerve lesions, the neurologists appropriated unto themselves the entire field of electrotherapy. On the other hand, the physical therapeutist recognizes that in the field of neurology electrotherapy plays only a very minor part. Diathermia, one of the phases of a faradic current, is indicated in every condition of disease where the natural forces seem to be inadequate. In tuberculosis pulmonalis it is almost a physiological specific.

Hydrotherapy is becoming better understood and is without doubt the best general therapeutic agent in the entire field of neurological diseases.

Dietotherapy in diseases of faulty metabolism, such as obesity, diabetes, nephritis and arteriosclerosis, is certainly our sheet anchor.

Psychotherapy, an agent not yet fully appreciated, promises much in the functional diseases. No better proof of the truth of this assertion is needed than to observe the effects of psychotherapy upon that large army, the Christian scientists.

Phototherapy, a much abused therapeutic agent, is slowly but surely coming into its own. The extravagant assertions made concerning the Röntgen ray, radium, and the ultraviolet ray are gradually subsiding. Most of these agents are understood by few, misunderstood by many, and underestimated by everybody. Instead of relegating them to persons not trained in anatomy, physiology, chemistry, and pathology, they should be tolerated only in the hands of medical men who are willing to equip their brains as well as their offices.

Not only that, but the application of these therapeutic procedures should go hand in hand with drug therapeutics. Physical therapeutics and drug therapeutics are not to be torn asunder, but are to be more firmly welded together. The one will be assisted by the other, they may even displace each other when used to produce physiological reaction. Our motto is: *"It is not the agent, but the reaction of living cells to an agent that must be our guide in therapeutics."*

It is daily being recognized more and more that the word, disease, is limited in its significance. Disease is the deviation of a process from the normal. Reactions by the system are processes to establish the normal. Physical therapeutics brings about normal physiological reactions, thereby assisting the economy to hasten or bring about in a normal physiological manner a process for the restoration of conditions previously existing.

There is nearly always a distinct feeling of opposition to the introduction of new devices, because physicians, like other men, walk in the path of least resistance; again, because of the inconvenience involved at having them at hand or the habits of accuracy demanded for their proper use.

We, therefore, who specialize in the application of the various physical therapeutic measures, owe it to the science of medicine to bring to realization the real merits of the agencies we advocate, for once they are introduced we wonder how we ever managed to do without them, but we realize how handicapped were preceding generations of physicians who knew nothing of them.

231 West Ninety-sixth Street.

Our Readers' Monthly Prize Discussions

Twenty-Five Dollars Is Awarded for the Most Satisfactory Paper

All persons, whether subscribers or not, are invited to compete for the prize of $25 offered for the reply deemed best by the editors to the following questions:

CLXXI.—How do you treat a sprained ankle? (Closed.)

CLXXII.—What are your methods of resuscitation and aftercare of persons apparently drowned? (Answers due not later than July 15th.)

CLXXIII.—How do you perform circumcision? (Answers due not later than August 15th.)

The award will be based solely on the value of the information contained in the answer. No importance will be attached to literary style. Answers should preferably contain not more than six hundred words, and should be written on one side of the paper only. All papers submitted become the property of the JOURNAL, and should bear the full name and address of the author for publication. The prize will not be awarded to the same person more than once within a year.

The prize of $25 for the best answer to Question CLXX was awarded to Dr. Henry J. Noerling, of Valatie, N. Y., whose paper appeared on page 27.

PRIZE QUESTION CLXX.

THE PREVENTION OF PERINEAL LACERATION.

(*Continued from page 29.*)

Dr. Louis L. Hoff, of Holyoke, Mass., states:

The perineum usually requires attention to prevent rupture, but there is no fear of laceration if the anterior border of it maintains a considerable thickness and is not fully on the stretch during the pain. Therefore no support is needed and nothing is required but to watch the progress of the head as it passes over the perineum. Advise the woman to refrain from bearing down, from holding her breath, pulling with her hands, pushing with her knees, etc. If she is unable to control her strainings, anesthesia is necessary. The methods of manipulation to prevent laceration of the perineum are too numerous to mention, but the principles involved, which are highly important to understand, are few and always the same:

First, give the perineum time to stretch by retarding expulsion; secondly, guide the head so that it may occupy as little space as possible. By keeping the plane of its smallest circumference parallel with the plane of the perineal ring through which it must pass, or, what is the same thing, keep the long diameter of the head at right angles to the plane of the perineum girdle. The central point of the occiput must lead; keep in the centre of the ring. Thirdly, relax the perineum as much as possible by gathering in tether from surrounding tissues; "give it rope" from the outside. The manipulations may be accomplished with the woman either on the left side or in the dorsal position, provided the lower limbs are not forcibly flexed or widely separated. Unreserved ocular inspection of the parts is absolutely required. In a good many cases I have noticed that rupture occurs at the moment or during the few moments of the last one or two pains, just as the head is being extruded. Normally the head is delivered by extension. The occiput arises over the mons veneris, while forehead, face, etc., successively emerge at the perineal margin. Hence, to retard expulsion, we must retard extension by pressure transmitted through the perineum upon the frontal bone, which indirectly retards expulsion. Extension must occur eventually or the child could not well be born; our purpose is to delay, not prevent it. When the perineum has time to stretch, we permit extension and consequent expulsion to take place. In the manipulation to carry out these purposes both hands are simultaneously used (the woman being either on her side or back—preferably the former) as follows: The right hand is so placed that its fingers rest upon the posterior part of the left labium majus, and the thumb upon the right labium, the web of skin between the thumb and index finger being above the line of the perineum margin. The left hand is passed over the abdomen and mons veneris until its finger tips come in contact with the occiput just beginning to protrude between the labia. During the pains the fingers of the left hand make direct pressure upon the advancing occiput in line with the long diameter of the head, to stop it from coming out, while the fingers and thumb of the right hand gather in perineal tissue from the sides, thus relaxing the central tension, while at the same time, aided by the palm and ulnar border of the hand, they transmit a deeper pressure through the perineum upon the forehead to retard extension. Meanwhile the manipulation unavoidably pushes the entire head toward the pubis, thus utilizing any spare space left between the pubic arch and the back of the child's neck.

During these proceedings the parts should be bathed occasionally with a hot solution of mercury bichloride and the hands of the operator washed in a similar fluid. When it is finally deemed advisable to allow the head to escape, let this occur if possible between the pains. Should the perineum escape rupture during the delivery of the head and neck, it may yet be torn during the passage of the shoulders. This may be prevented by lifting the head and neck up toward the mons veneris so that one shoulder goes back behind the symphisis pubis, while the other escapes at the coccyx. This enables one shoulder to be born at a time and produces less strain upon the perineum than when both are pulled out together, which must be avoided.

Dr. Jesse D. Friedmann, of New Kensington, Pa., writes:

Our aim in preventing this condition should be the close observance of Nature in the normal mechanism of labor and the elimination of the

causes producing laceration, such as rapid delivery, forceps, large fetal head, occiput posterior positions, etc. As lacerations occur during the second stage of labor, our attention will be devoted to this period.

The desideratum in the normal mechanism is to secure the smallest possible diameters of the presenting part to emerge through the parturient outlet. In vertex anterior positions, the external occipital protuberance should have passed the subpubic arch before we allow the head to extend, so that the smallest suboccipitobregmatic circumference engages and passes the outlet. Abundance of time must be given to the muscles of the pelvic floor to stretch sufficiently without tearing to permit of the passage of the fetus. I often employ digital stretching of the pelvic floor preliminary to the descent of the presenting part, so that a relaxed condition of the muscles will await the latter when it reaches the pelvic floor. Chloroform or ether to the obstetric degree will also assist in this relaxation when the head is ready to be born.

Our object is to obtain stretching rather than tearing. To do this we prevent too rapid advance of the head; the patient is not to bear down, to breathe rapidly during pains, to cry out during the emergence of the head. We use manual retardation of the head until it is ready to be born, and use chloroform or ether. Partial anesthesia relaxes the tissues and prevents too rapid advance and expulsion. We must remember that our object in protecting the perineum at this stage is more to bring pressure to bear on the head rather than on the perineum. The delivery of the head should be accomplished between pains, the advantage being that we have a relaxed instead of a rigid pelvic floor at this time.

Having considered the preliminary principles and theories, we can now proceed with the actual method of protecting the perineum in childbirth. The posture during the second stage differs with the ideas of the accoucheur, but the principle is the same—control and delay of the advancing head or presenting part of the child by direct manual manipulation to gain the advantage of the elasticity of the perineum. Some use the dorsal posture, others the lateral prone—the left for left positions, the right for right positions of the presenting part.

In the lateral position of the patient, the physician standing to the right of and behind the patient, uses the fingers of the left and right hand in controlling the head; or he may use the left hand for control of the head, the fingers of the right hand embracing the bitemporal diameter of the fetal head from the perineum on either side of the coccyx. In the latter method the presenting part is pushed up close to the subpubic ligament. Here again chloroform or ether (partial anesthesia) is of aid.

In the dorsal posture, the right hand is used for perineal protection. The middle finger flexed on the palm is placed behind the anus (not entering the latter) and in front of the coccyx, thus bringing pressure to bear upon the forehead of the fetus. The thumb over the right and the index finger over the left labium majus grasp the parietal eminences. The fingers of the left hand control the presenting part in the vagina. In this manner the presenting part is under complete control and can be advanced or retarded at will. The pressure over the parietal eminences prevents too sudden advance of the head, while the middle finger of the right hand presses on the forehead. Thus when the pelvic floor has sufficiently relaxed, the head may be extended (only after the external occipital protuberance has passed the subpubic ligament) and shelled out of the vulval orifice.

We often find that after the delivery of the head without a tear, the aftercoming shoulders produce just what we have been trying to prevent—laceration of the pelvic floor. I believe it is just as important closely to observe the mechanism of shoulder delivery to prevent laceration, as it is to manage the birth of the head. Delivery of the shoulder should be delayed until complete rotation of the bisacromial diameter has taken place. The anterior shoulder is best brought behind the symphysis and the posterior shoulder allowed to be born first. This secures the cervicoacromial diameter at the outlet. Some deliver the anterior shoulder first, but our aim in either case should be to get the shortest diameter of the shoulders to pass through the vulva and not to permit the shoulder to press too closely against the perineum, being rather pushed carefully into the pubic arch.

Adhering to the normal mechanism of labor, correcting abnormalities so as to bring about normal mechanism, the use of chloroform or ether to the obstetric degree, and the delivery of the presenting part during perineal relaxation (between pains) while the fingers control the advancing head, is our desideratum and will in the majority of cases be productive of an intact pelvic floor. It will not be amiss here to mention that an empty rectum and bladder facilitate the progress of labor and minimize the possibility of perineal laceration. Where, however, a pelvic laceration must occur (old primipara, large head, etc.), all attempts failing and conditions not permitting further delay, episiotomy properly performed, is preferable to a perineal tear.

Dr. J. Otis Carrington, of Malden, Mass., observes:

A serious laceration of the perineum is usually the result of carelessness or lack of skill. The elasticity of the pelvic floor should be allowed to develop to the utmost, and this can be done if the advance of the presenting head is controlled so that it will be gradual and complete. Furthermore, the advancing head should be delivered in the interval between the pains, and if in the agony of pain efforts become too expulsive, they should be controlled by anesthetics. Control of the advancing head is obtained by directing attention to the rapidity of expulsion. This control is maintained by using anesthesia and external pressure.

We should remember to keep the shortest diameter of the presenting part across the parturient canal. Thus, in a vertex presentation, we keep the head well flexed until the suboccipitobregmatic diameter has passed the pelvic outlet before extension is allowed.

In some cases, however, there will be a laceration, notwithstanding perfect obstetrical technic.

Sometimes no cause can be found. Again, there are conditions in the patient that are responsible for the tear: Edema, excessive deposition of fat, white cell infiltration from syphilis, lack of elasticity from previous operations, age, and constitution. Any such causative condition must be sought for during the latter period of gestation and remedied as far as possible before labor sets in.

Preservation of the perineum is of the greatest importance to the patient as well as to the obstetrician. It ranks in importance next to the preservation of the lives of mother and child. Too frequently it happens that in a normal case of a young, healthy primigravida, a serious laceration occurs because of the haste of the attending obstetrician. Unnecessary haste cannot be too strongly condemned.

We are sometimes justified in delivering rapidly as in a breech presentation and where the child is threatened with asphyxia. In delivering a breech, rotation of the head forward, as it passes through the outlet, will help to prevent tears.

Exit of the head in unfavorable attitudes—as in face, brow, forehead, and posterior rotation of the occiput—will cause a laceration because the most favorable circumferences are not presented to the canal unless such conditions are determined before the onset of labor and correctly managed during delivery. A large child overstretches the pelvic outlet. Labor should not be hastened without positive indication.

There are many good reasons for and against episiotomy. Nevertheless, it has its place. When labor is at its height and the perineum is so tense that it obstructs the completion of labor so that delivery of the head seems impossible without an extensive tear, episiotomy has a limited field of utility. It is much better deliberately to cut the vaginal ring to allow the completion of labor and then suture than to stand helplessly by and watch the perineum tear in an ugly fashion and perhaps deeply into the sphincter ani; or to be rudely awakened several months later to the presence of a submucous laceration that will require a secondary perineorrhaphy.

Forceps should not be indiscreetly applied, but when their use is indicated they are one of the best means of preventing rupture, for the head can be restrained during the height of the pains and the degree of tension regulated.

Dr. S. H. Ensminger, of York, Pa., states:

Prophylaxis depends upon the cause. If there is great disproportion in size or abnormal rigidity of the outlet, abundance of time must be allowed the muscles of the pelvic floor to stretch sufficiently without tearing to permit of the passage of the fetus. Preliminary digital stretching as well as the use of chloroform or ether will assist in the relaxation of these muscles, and if all attempts fail and conditions do not permit of further delay, episiotomy, properly performed and repaired, is preferable to deep rupture. The chief ends in view are: 1. To prevent too rapid expulsion; 2, to preserve the normal mechanism of delivery, or to convert a faulty presentation into a normal one; and, if possible, 3, to effect delivery of the head between the pains.

To protect the perineum, we empty bowel and bladder and place patient in the left lateral prone posture for left position of the presenting part, and the right lateral prone posture for right positions. The lateral posture is most favorable to perineal preservation. In this position the force of violent pains is diminished, since the expulsive power is actually a resultant of two divergent forces. The intraabdominal pressure is also weakened, and the perineum is always under ocular control. In the dorsal posture the weight of the head carries the latter away from the pubic arch and against the perineum; this condition is not favorable to the perineum. While this disadvantage may be offset by the upward pressure of the posterior segment of the perineum toward the symphysis, the former thereby becomes ischemic, thin, and more prone to rupture. In the lateral prone posture care must be taken that the thighs are not too energetically flexed, otherwise the perineum will be put upon a dangerous stretch. After delivery the lateral posture must be quickly changed to the dorsal lest air embolus result.

I always place the patient in the lateral prone posture. In the left lateral posture the right, and in the right posture the left hand is used for perineal protection. In the left lateral posture the physician seated at the beside behind the patient, passes the left hand and forearm over the right thigh of the patient and uses the fingers of this hand to retard the exit of the presenting part, and also to assist to a small extent the normal mechanism of labor until the pelvic floor is sufficiently stretched to allow the passage of the fetus without laceration. At the same time with two or three fingers of the right hand placed upon the protruding head, and without touching any part of the maternal tissues, control of the expulsion and regulation of the head movements can readily be carried out. Both hands are used to control a too rapid advance and conjointly to regulate the head movements, so as to secure the most favorable mechanism of head delivery.

Or we place the fingers of the right hand on each side of the coccyx, over the extremities of the bitemporal diameter of the fetal head. The presenting part is pushed as close to the subpubic ligament as possible, thus making use of all the available space of the pubic arch. Chloroform or ether to the obstetric degree, and delivery of the presenting part during perineal relaxation between pains, by pressure with the fingers on either side of the coccyx, will greatly lessen the danger of rupture.

Or with the patient in the lateral posture, the physician seated alongside the bed facing the woman's vulva, the outspread hand, which can most conveniently be used for the purpose and protected by a hot sterile towel, is applied to the distended perineum so that the thumb and forefinger encircle the posterior commissure of the vulva. This hand helps to flex the head when the occiput is anterior; it restrains the progress of the head, and pushes it forward under the arch of the pubes. The other hand is applied to the fetal head and used as described above.

In the dorsal posture either hand is available. By the natural forces or by pressure upon the fundus the head is made to distend the vulva sufficient-

ly to enable the middle finger of the perineal hand to obtain a point of pressure upon the forehead of the fetus by reaching behind the anus, but without entering the rectum. The thumb of the hand is then placed upon one labium majus and the index finger upon the other over the parietal protuberance of the advancing head, thus drawing the labia inward and backward and preventing undue strain upon the posterior commissure. Pressure of the fingers upon the parietal eminence prevents the too sudden advance of the head, while the middle finger, reaching behind the anus and protected by a sterile towel, exerts pressure upon the forehead, and at the proper moment during relaxation between pains, increases extension of the head and slowly shells it out through the vulvar opening.

Perineum preservation during the delivery of the shoulders is best attained by preserving the normal mechanism of shoulder delivery. Delivery of the shoulders should be delayed, if possible, until nearly complete rotation of the bisacromial diameter has taken place. The head should be held in the hand and gently raised so as to bring the anterior shoulder well up behind the symphysis, thus securing the cervicoacromial diameter of the fetus instead of the bisacromial at the outlet. The posterior shoulder is thus permitted to be delivered first, and should be carefully guided in its passage over the perineum. Shoulder delivery should be accomplished whenever possible by the natural forces, since manual extraction increases the number of perineal lacerations.

Sarwey in Winckel's *Handbuch* (12, 1904) gives some fifteen different methods of supporting the perineum. None insures the woman against injury. The methods enumerated I have found to be the most satisfactory, and with proper care perineal laceration ought to be rare. All are agreed, however, that lacerations should promptly be repaired, since failure to do so is responsible for a large percentage of gynecological cases.

Dr. C. C. Henin, of Springfield, Mass, writes:

Numerous procedures have been proposed for the prevention of perineal injuries during injury, but there is probably no portion of the female anatomy more difficult than the pelvic floor, known as the perineum.

In order to prevent lacerations of the perineum we must promote relaxation of the pelvic floor and lessen the tension to which it is subjected during birth. On the appearance of the slightest danger of laceration, chloroform or ether should be given. By the proper use of the anesthetic the strength and frequency of the pains and the rapidity of expulsion may be regulated at will.

The advance of the head can be controlled by pressure with the thumb and finger held upon the occiput. To keep the tension of the vulva at a minimum the long axis of the cephalic cylinder must be kept at a right angle with the plane of the outlet of the soft parts. All these manipulations are best conducted with the patient in the left lateral position. The patient is placed upon the left side, with the buttocks close to the edge of the bed, as soon as the head has reached the floor of the pelvis. With the finger upon the perineum just behind the posterior vulvar commissure, the occiput can be felt through the soft parts some time before it begins to distend the perineum; the patient lying upon the left side close to the edge of the bed, the operator, sitting behind her, grasps the head with the fingers of the right hand placed just in front of the fourchette, while the left hand, passed over the abdomen and between the thighs of the mother, seizes the occiput.

Next in order of prevention of laceration of perineum comes episiotomy. The instrument required is a blunt pointed tenotomy knife. When laceration seems inevitable, the cordlike ring, which can be felt about half an inch above the tense border of the vulva by examination during a pain, should be divided. The operation is performed on each side. The length of the incision should be about one inch, its depth one quarter inch. Most essential is that the cuts be made parallel with the long axis of the mother's body, not with the vaginal axis. After labor the cuts should be reunited with stitches. The wounds may be closed without waiting for the delivery of the placenta. In conclusion, I would say that precaution must be taken to prevent laceration of the perineum, 1, by making firm backward and upward pressure against the occiput during pains; 2, by restraining voluntary expulsive efforts during pains; 3, by securing expulsion of the head between pains; 4, by giving little chloroform or ether during severe pains; 5th and last, by resort to episiotomy.

Contemporary Comment

Treatment of Syphilis: A Gift to the London Hospital.—The International Medical Congress of 1913 and the appointment of a Royal Commission to inquire into venereal diseases focused public attention on the treatment of these conditions in a remarkable way, and the issue of a sensible report has confirmed the interest now being manifested. A valuable step toward the better provision of opportunities for treatment was taken in February, 1914, when the Grocers' Company offered to defray the cost of building and equipping a ward at the London Hospital for the treatment of syphilis. It was then determined by the authorities, according to the *Lancet* for May 27th, to add another floor to the existing isolation block of the hospital, and this step, owing to structural difficulties in the work, cost £10,000. The building was delayed on account of the war, but was completed by the end of 1915. Financial stringency led to a decision to delay opening the ward until the end of the war, but owing to the great increase in the number of patients presenting themselves for treatment the house committee found it necessary to open the new department on March 1st last, the ward being worked in connection with the skin department of the London Hospital, as it is intended at first to make special study of the treatment of syphilis in the acute infective stages. The ward, which is admirably constructed, contains eight beds for men and eight for women, all the patients being in separate rooms. A well equipped laboratory for clinical investigation, together with bathrooms and suitable accommodation for nurses, makes the whole building a model for its purpose.

Dietetics, Alimentation, and Metabolism

Food and Food Preparation, in Health and Disease

FOOD, DRUGS, AND LONGEVITY.

Some Thoughts on Their Relations,

By Leroy D. Swingle, Ph. D.,
Department of Pharmacology, University of Utah.

The primary desire of the human race is happiness, and the most fundamental requisites for happiness are health and life. Sickness and death, more than all other factors, stand in the way of its attainment. The medical profession, existing avowedly for the curing of disease and the preservation of life, assumes the guardianship of the most valuable property of the human family. The saving of life involves, not only the curing of disease, but more fundamentally its prevention; and so the physician requires, beside knowledge of the best therapeutics, a knowledge of effective prophylaxis, which involves heredity, environment, and food.

Doubtless this thought has often come to every one of us: Since the functions of man's body may be maintained automatically for seventy-five or 100 years, even under adverse conditions and among limitless besetting dangers, why should they not be maintained for 1,000 years, or even everlastingly under ideal conditions?

There appear to be three fundamental factors limiting the life of man. They are: 1. An imperfect organism, including the life principle, if there is such a thing; 2, environment adverse to protoplasmic activity, necessitating a struggle for existence; and, 3, imperfect food. It may be asked, What is meant by "imperfect organism"? Since, to our mind, there exists at present no perfect human organism, we cannot define the imperfect by comparing it with the perfect. Hence it becomes necessary to define a theoretically perfect organism. Such may be conceived to be a body, not only exhibiting all the necessary functions, but also containing them in the harmony or balance required to insure continued existence. Under the present adverse conditions the human body manifests the sufficient functions and possesses them in such balance as to maintain its existence seventy-five to 100 years. We can conceive that a more nearly perfect functioning might enable it to maintain its existence many times longer even under present conditions. Carrying our thought further, the theoretically perfect organism is one capable of preserving its existence forever, provided that its environment and food materials are ideally perfect. An imperfect organism is one that does not meet these requirements. The human body, we believe, is such, and would die, even though the last two factors were perfected.

Moreover, there are in the human body definite evidences of imperfections. Who dares say that vestigial organs, such as, for example, the appendix, are not such evidences? True, the biologist would say that vestigial organs are present as functionless remains of organs whose functions were no longer needed or useful. Yet, is it not as logical to suppose that the organ was lost as a result of some deleterious action on the characters of the germ plasm, causing the organ to be imperfectly developed, and that the animal survives in spite of the loss of that function. Were an organ, like the heart, which is absolutely necessary to life, so poorly developed, it would mean the extinction in one generation of the race, provided that the defect was universal. Who can say that man would not live much longer, if all his vestigial organs were functioning perfectly? It is conceivable, at least from the standpoint of Darwinism, that the functioning of the muscles of the ear would give man a little more advantage in avoiding danger, and that an olfactory organ as perfect as that of the dog would be in many ways an advantage, especially since it has been proved that poisonous food may be associated with odors. We recognize that the lower animals exhibit many of the same functions as we, but much more perfectly. This in itself proves that some of man's functions are not perfect. Our thought is that vestigial organs may just as well represent imperfections, resulting from the impairment of more perfect organs, as that the organs degenerated because their functions were no longer needed or useful.

The problem of determining what would constitute a more perfect organism, and how to obtain it, belongs more particularly to the biologist. It is largely a question of heredity. The physician's problem has mainly to do with the organism as heredity brings it to him, although he stands in position to aid in the production of a more nearly perfect organism. This could undoubtedly be accomplished by artificial selection from families that show great longevity, environment and food conditions being equal. While there is nothing about artificial selection that would remove the defects, known or unknown, which are universal in the race, yet it would remove those which are not universal by propagating the individuals free from them. This improvement in the organism would raise the average length of life nearer to that possessed by the most nearly perfect. Any further increase would necessarily need to come through an amelioration of environment and an improvement in food conditions.

No one will question that environment contains many things that are unfavorable to life; many are being discovered and the results are being applied by the physician. The fruits of sanitation, which is removing many of the injurious elements of environment, are appearing in the form of a rise in the curve of the average length of life. Doubtless the researches of the next century will reveal many more undesirable features in the environment of man. The knowledge of them guarantees their removal in time.

Though the organism should be improved and the environment perfected, still the maximum possibility of health and longevity would not be reached. The body is a complex automatic laboratory, delicately correlated. This correlated automaticity

is a most characteristic property of living beings. A fire burns on automatically as long as suitable fuel and oxygen are supplied. But this is nothing compared with the complicated automaticity of living bodies. Not only is there a complex activity in each cell, but millions of various kinds of cells are combined so as to produce a grand unity of activity, which commands the wonder and admiration of all who study it. If new materials are not supplied for the laboratory processes, the activity is interrupted, and finally the correlation is irredeemably destroyed, death ensuing. Hence, while the bodily functions are automatic, they do not violate the immutable law of the conservation of energy by exhibiting that impossible phenomenon of "perpetual motion." But automaticity is a different thing, and there appears to be no reason why it should not be maintained, instead of one hundred, one thousand years, provided that, along with the improvement of the correlation of functions, food materials, a little better adapted to the life processes, were furnished.

It is not unreasonable to suppose that the less ideal the food materials supplied, the quicker will the correlated processes break down and death ensue, and this, despite the fact that this wonderful laboratory exhibits adaptability. It has the power within limits to dispose of unwholesome or unnatural substances thrust upon it, so that little or no immediately apparent harm is done, though, it must be remembered, remote effects may be produced that have not been as yet associated with the diet, which is the real, the primary cause. However, there are certain elements absolutely essential to its functions which must not be omitted from the diet. The effects of a diet lacking or deficient in these materials are manifested in serious pathological changes. Beside such easily recognizable essentials as the proteins and certain salts, other obscure elements may be necessary to perfect function. An example of these is furnished by the vitamines, the most striking instance of their role being presented by the disease, known as beriberi. This recent discovery is enough to lead us to think modestly of our knowledge of the food requirements of the complicated human organism. It is quite possible, therefore, that the best diet known at present may fall short of the optimum supply for the body, and may thus cut the life short of what it would be with a perfect food. Causes which are so slight and which act so slowly as not to produce noticeable effects, might during a lifetime accumulate sufficient action to injure one or more organs and destroy the grand correlation of functions, finally producing death. In other words, death at a hundred years may not be solely the result of an absolute limit determined by heredity, may not be due merely to an adverse environment, nor even entirely to a combination of heredity and environment, but possibly in large measure to imperfect food conditions, although the diet be the nearest ideal that chemistry and physiology can at present prescribe. There are hopes, therefore, that further investigation along the line of dietetics will reveal the fact that some important substances are lacking or are not ideally proportioned.

In support of this idea we would mention Woodruff's (1, 2) work on the paramæcium and Child's (2) experiments with the planaria. The former author found that senesence and decay could be prevented by changing the food occasionally. He also discovered that it was not even necessary to alter the food, but that the same results could be obtained by the use of Liebig's extract of beef. Under these ideal conditions, conjugation, the ordinary method of rejuvenation, was not necessary to prevent senility and death. Child found that he could prevent senesence and fragmentation in the asexual generations of planaria by carefully regulating the kind and quantity of food so that the animals were held at a certain size.

Another line of argument bringing us to the same conclusion may be presented. The question arises, Why does the germplasm live on for thousands of years, while the somatoplasm dies with each generation? Here we have positive knowledge that one type of protoplasm, the germplasm, has maintained its life for thousands of years. Why, then, should not the other type, namely, somatoplasm, which is by cell division the genetic product of the germplasm, live on and on? It is primarily the daughter and secondarily the sister of the germplasm.

If it can be determined why the germplasm exhibits so much greater length of life than the somatoplasm, a suggestion might be given as to how the life of the individual can be lengthened. Of course it might be conceived that the elements conferring the property of longevity—if there is such a specific property—are distributed early in the process of cell division to the cells which constitute the germplasm so that the germplasm inherently possesses the property at the expense of the somatoplasm. Consciousness is exhibited only by the brain cells of the somatoplasm, and therefore our conscious life and interests are intimately bound up with the interests of the somatoplasm. But longevity, the very thing that our happiness demands, especially when we reflect that longevity necessarily means less sickness than we are accustomed to, is exhibited by the germplasm, which cannot enjoy it. This is "vexation of spirit," as the wise man declared concerning life, for says he, "Yea, I hated all my labor which I had labored under the sun: because I should leave it unto the man that shall be after me, and who knoweth whether he shall be a wise man or a fool?", who, we might add, may destroy it in beastly war, as is the present custom. However, the germplasm, at least in higher forms, continues it existence only on condition that it is mixed in each generation with other germplasm from the opposite sex. Hence it is probable that the germplasm does not enjoy longevity at the expense of the somatoplasm. It may not inherently possess any more longevity than somatoplasm. The life of the germ cell, unless it unites with another germ cell from the opposite sex, generally is not continued any longer than that of the individual. It might be argued, therefore, that the soma would live on and on, if there was some means of repeatedly rejuvenating it by incorporating into it other living somatoplasm in such way that both would lose their identity and form a new individual, as in the case of the sex cells. But the somatoplasm

can incorporate only dead materials which are taken in as food, while the older the person, the less the tendency to be rejuvenated by food. A similar condition is seen in the protozoa, which exhibit this same tendency. Yet, the only thing necessary to prevent senility and consequent death, is to change their food, or as recent experiments show, provide a more perfect food. Here is a hint that senility and death are closely related to diet, suggesting that senility and death of the somatoplasm in man is not inherent, but is due to a lack of proper food conditions. The germplasm lives on only because it is rejuvenated in a way quite comparable to food rejuvenation in the protozoa. This statement appears more justifiable in view of the facts regarding artificial parthenogenesis in which there is no incorporation of other living germplasm. We mention artificial parthenogenesis here instead of natural parthenogenesis because it serves as a better illustration of the point in question, since it is brought about in germplasm which naturally requires fertilization with male germplasm. In artificial and in natural parthenogenesis we have examples of the germplasm being rejuvenated with conditions other than the incorporation of other living germplasm. And on the other hand, even in the higher plants, indefinite propagation of the somatoplasm may be accomplished. But it might be asserted, in accordance with De Vries's theory of pangenesis, that the reason why the somatoplasm in such cases can be propagated is to be found in the possibility that the somatoplasm and germplasm are not completely differentiated, that the somatoplasm contains germplasm. But in the mammals, where the germplasm may be more completely differentiated from the somatoplasm, Rous and Jones (4) assert that somatoplasm cells may be propagated indefinitely by subculturing them, involving a change of food conditions.

(*To be continued.*)

A Study on Food.—R. J. Wilson and W. L. Rathbun (*Journal A. M. A.*, June 3, 1916), have studied the dietary question as it presents itself in institutions for the care of the sick, more especially those for the treatment of tuberculosis, and publish their findings. Their conclusions are as follows: 1. In all institutions for the care of the tuberculous, food studies, including the caloric content of the dietary and food waste, should be carried on at regular intervals, preferably for one week or more during the various seasons of the year, and these records should be made available for comparative purposes. 2. Special training, though advisable, is not a necessary requisite for the carrying out of a successful dietary study in an institution. It is, of course, essential that the doctor who directs the work should be thoroughly familiar with the problem. It is only necessary that the person or persons who are doing the work should be intelligent, careful, and willing to follow conscientiously the rules of the game. 3. The elimination of meats and eggs from the morning meal and the substitution of milk is a sound and justifiable economy. 4. The dietary of the tuberculous should be high in caloric value, but confined to three daily meals in all but exceptional cases. 5. Males consume more food than females, both in total amount and in number of calories to the pound of body weight, but in spite of this fact, females make much larger gains than males, enough so as to indicate that rapid accumulation of weight is a characteristic of the female sex. 6. The avoidance of frequent repetition of foodstuffs is important. 7. A four weeks' menu, when used as suggested, is of great aid to those controlling the dietary, and tends to do away with repetition. 8. The treatment of small children, in separate units, in institutions with adults, is both feasible and advantageous in that it results in economy of foodstuffs. 9. Small initial servings with as many seconds as may be desired is satisfactory to the patients and prevents much plate waste. 10. The plate waste in institutions for the tuberculous is of necessity higher than in hospitals for the insane or in general hospitals.

Diet in the Treatment of Pulmonary Tuberculosis.—David C. Muthu (*Practitioner,* June, 1916) says that it is time for us to recognize that it is impossible to formulate a standard diet suitable to all tuberculous patients, for they differ in age, temperament, height, and weight, in the conditions of their disease, and in their digestive capacity. A diet constituted upon scientific calculation as efficient and satisfactory does not always work out correctly in every day practice. In theory, the value of food can be estimated in grams and calories, but in practice it depends, among other factors, upon, 1, the physical properties of the food stuffs; 2, the assimilative power of the digestive organs; 3, the condition of the patient. The chemical analysis of food stuffs differs as they are fresh or stale, green or dry, and this applies to fish, milk, eggs, meat, fruit, and vegetables, so that the fresher the food, the more easy and rapid is it of digestion, and the more nutritive its value. The stomach should have four hours of rest between meals, and, generally speaking, no food should be given between breakfast, dinner, and supper, though a cup of tea with one thin slice of bread and butter at four o'clock in the afternoon, is often advisable. Overfeeding is both unscientific and injurious, and is apt to induce dyspepsia and other gastrointestinal disturbances. A furred tongue, a bad taste in the mouth, constipation, headache, with slight pyrexia and sleeplessness are symptoms that the patient is having more to eat than he can digest, and his diet should be cut down. Patients with weak digestion especially should not be overfed, and sometimes it is well to try two meals a day. An exception must be made in patients who have more or less normal powers of digestion, but who are small eaters, who have persuaded themselves that they cannot eat much solid food and so have got into a weak, neurotic condition. The nutritive value of food depends also on the physical and mental condition of the patient. One who takes his food with pleasure will assimilate it easily, while one to whom the food is repulsive will digest it with difficulty and distill toxins from the most nourishing. In arranging diet, the mental condition and temperament of the patient must be taken into account, along with habits of life and idiosyncrasies.

Dietetic Treatment of Diabetes Complicated by Nephritis.—Henry S. Stark (*Med. Record*, June 3, 1916) says that his records show that after the fifth year of diabetes, nephritis occurs in thirty-five to forty per cent. of the patients. One sided diet must not be continued too long, as acidosis or coma may follow a starch free diet, while intestinal intoxication may follow a continuous protein diet. A diabetic who assimilates meat poorly is worse off than one who assimilates starches poorly. Overindulgence in fats may result in emaciation, toxic fatty acids in the urine, and fats in the stools, with intestinal symptoms from faulty fat metabolism. Salts cannot be allowed *ad libitum*, especially when signs of edema appear. Starch free diet is dangerous over long periods, and the degree of carbohydrate tolerance must be found and followed rather than than that the sugar index of the urine should be the sole guide. Karell's diet is of value when edema is marked, with the addition of two or three eggs a day. Allen's starvation method in Stark's hands showed sugar free urine in four to seven days in seven of twelve cases, while the other five resisted the treatment. Overfeeding must be avoided and the renal and cardiac functions require constant watching. The blood pressure curve is a guide to treatment, for when a diabetic is drowsy or has headaches, with increasing blood pressure, accentuated second aortic sound, and increasing albuminuria, the nephritis needs more attention than the glycosuria. If there is no steady rise in blood pressure, however, no cardiac hypertrophy, no evidence of arteriosclerosis, then the glycosuria should be treated, always seeking to avoid ketonuria.

A Diet to Prevent Pellagra.—The diet recommended for the prevention of pellagra will not produce results if followed for a week or ten days only, but if continuously and consistently used, under circumstances similar to its administration in the various institutions where the experimental tests have been performed, it will protect against the disease. Necessarily, a rigid unvaried diet is wholly undesirable and the menu recommended is only to indicate in a general way the character of the food to be prescribed. Frequently the element of poverty, inaccessibility to market supplies, or even personal idiosyncrasy, may require some modification of the diet table, so that strict adherence to its components may not in all respects be practicable. The object of the diet as submitted is to minimize the consumption of the carbohydrate (starchy and sweet) foods and to increase the amount of fresh animal protein and of fresh legumes (peas and beans).

The breakfast, for example, observes the *Medical Summary* for May, 1916, should consist of oatmeal and cream, without sugar, with either ham or breakfast bacon and two eggs. Not more than two thin slices of whole wheat bread should be taken, preferably untoasted. Hot bread or biscuits are inadvisable. A glass of fresh milk is to accompany the breakfast, and either oranges or grape fruit may be the initial course. The dinner should consist of either pea or bean soup, prepared from dried peas or beans, with a meat stock. The meat may be beef, pork, ham, chicken, veal, or mutton, prepared in whatever manner is the most appetizing, preference being given to roasting or broiling rather than frying. Hamburger steak, meat hash, or fish may be substituted to afford variety. Care should be exercised that the meats are not overdone. Of vegetables, Irish potatoes, boiled in the jacket or baked, cabbage, turnip or mustard greens, collards, and lettuce, are to be recommended. For dessert, stewed fresh or dried fruit will prove sufficient. The dinner should be accompanied by not more than two thin slices of whole wheat bread and a glass of buttermilk. The supper should consist of pork and beans, or baked beans properly seasoned, the usual amount of bread, and a glass of buttermilk. If preferred, eggs, scrambled or otherwise prepared, may be substituted for the more substantial ingredient of the meal.

Such a diet is not prohibitive as to cost, at least to but few of the residents of the country, affords a sufficient number of heat units, if taken in reasonable quantity, and will effectually prevent the development of a disease which caused 8,000 deaths in the United States during the past year.

Esthetic Merchandizing. Deficiencies of Artificial Foods.—At a meeting of the National Clean Milk Society, held in London on April 12th, Lord Plunket suggested that firms supplying clean milk should supply it in attractive bottles in Greek designs, instead of the present ugly vessels. Ladies might turn their attention to designing covers such as those used for bringing champagne bottles to table, and thus give an artistic pleasure to a utilitarian beverage.

Sir Thomas Barlow, according to the *Medical Press and Circular* for April 26, 1916, spoke on the failure of the various tests to produce a good imitation of mother's milk during the past twenty-five years, the greater number of infants' foods being deficient in fats. There should be as little tinkering as possible with fluids intended for children. As the sterilization of milk and the use of dried foods spread in upper class nurseries a new form of malnutrition or infantile scurvy, similar to that from which sailors on long sea voyages without fresh food used to suffer, was seen. A speedy recovery was found on giving fresh milk, a little orange juice, and a little gravy. Milk should be pure, even if it was sometimes diluted or modified, but it must not be tinkered with. There must be cleanliness of the byre (cowshed), the cow, the cow's food, the vessels from which it drank, and the hands of the milker.

Dietetic Treatment of Bronchial Asthma.—According to Allan Eustis (*Southern Medical Journal*, May), all animal proteins, with the exception of buttermilk, should be eliminated as much as possible from the dietary in the treatment of cases of paroxysmal dyspnea with prolonged expiratory murmur and great expiratory effort, in which there are sibilant rales over both lungs, called bronchial asthma, whether associated with cardiac disease or not. He considers that most of these cases are due to absorption of proteolytic toxins, which may come from a suppurating accessory sinus, an alveolar abscess, or the intestinal canal, and that the treatment of the intestinal toxemia is as important as the drainage of a fecal infection. Care must be taken not to make the diet too restricted, as in that case symptoms of pellagra may develop.

INFANTILE PARALYSIS.

A condition approaching panic has been excited in certain parts of the city by the remarkable outbreak of acute anterior poliomyelitis, commonly known as infantile paralysis. As pointed out, however, by at least one temperate lay thinker in the daily press, when we think of the population of the greater city, almost 6,000,000, the number of cases reported lose much of their impressiveness. It is remarkable that although infantile paralysis has been a regular summer visitor to New York for many years, we have learned little or nothing of its etiology or treatment during at least a quarter of a century. In 1890, to our personal knowledge, the slowly interrupted galvanic current was used at the outdoor clinics on the disabled limbs—usually the lower—while parents were instructed to wrap them in cotton batting to secure warmth, and to massage the affected muscles morning and evening. Occasionally strychnine was exhibited. Today little if anything more is done, although the department of health has given excellent advice regarding prophylaxis. We believe that this would be an opportune time to lay stress on the danger of domestic pets acting as carriers.

THE ETIOLOGY OF IRITIS.

A generation ago the etiology of an iritis gave us little concern; if it was not traumatic, secondary to some other inflammation of the eye, or did not occur during the course of some acute infectious disease, we rested content in ascribing it to syphilis or rheumatism, dividing the cases about equally between the two diseases. If the patient had ever been so unfortunate as to acquire syphilis, the fact was enough. If he happened to be rather young and denied that he had ever had the disease, we were inclined to be skeptical, even though we could find no stigmata, unless he had a distinctly rheumatic history. In an elderly patient, indefinite muscular and joint pains, such as few of us have been lucky enough to escape, were held to furnish a sufficient explanation. The same happy go lucky method of differentiation prevails to a great extent today. With many physicians a history of venereal exposure is sufficient, a positive Wassermann ample evidence of the syphilitic nature of the inflammation, and when this is wanting rheumatism continues to bear the blame. This method, however, of arriving at the etiology does not stand the test of careful investigation. Years ago doubt began to be expressed as to the correctness of the diagnosis, and more painstaking studies of the patients were instituted, with results that seem almost revolutionary. Syphilis remains prominent as a factor, but in a greatly reduced proportion of cases, while rheumatism has practically disappeared as a cause. Its place has been taken by a number of focal infections that have been proved to be responsible for a large proportion of the cases of inflammation of the iris, although they were referred to only in a few isolated cases a few years ago. The change that has taken place in the opinions of the best informed concerning the etiology of iritis is exemplified by the paper by Irons and Brown (*Journal A. M. A.*, June 10, 1916).

Careful attention was given to the histories of one hundred patients suffering from iritis, who were then subjected to a thorough physical examination, including Wassermann tests controlled by two laboratories, complement fixation tests, tuberculin tests, cultures of pus from infected tissues, and röntgenographs of teeth, sinuses, and lungs, to detect the presence of syphilis, tuberculosis, gonococcal infection, and infections of the teeth, tonsils, accessory sinuses, prostate, pelvis, and other structures. Measures were then taken to remove all infections

so far as possible, and valuable evidence as to the etiology was obtained from the course of the iritis after these procedures. Two or more infections were found in many of the patients, in some of whom the actual etiological factor could be determined, while in others it could not. The cases in which the actual cause was uncertain were included under the head of combined infections.

Sixteen of the patients in whom the iritis was not due to syphilis had nevertheless acquired the disease, a fact which shows how little dependence can be placed on a history of syphilis, and even on a positive Wassermann, in the absence of active symptoms, in determining the etiology. Superficial lesions and suppurations about the teeth and tonsils were not found to be at fault; the foci were deeply situated in every case. So far as we can judge from the results of these careful studies, the principal cause of an iritis seems to be a focal infection somewhere in the body where bacteria live and multiply, whence they enter the blood stream and are carried to the iris. The proportionate number of cases in which the focus may be in any one place obviously cannot be determined from so small a number as one hundred, but the number these writers found situated in the teeth and tonsils is striking. The paper is illuminating.

DIET IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

It is obvious that diet is one of the most important factors in the successful treatment of pulmonary tuberculosis, and it seems that so much has been written concerning this phase of the subject that there is little or nothing to add. While on the main principles of the dietetic treatment of tuberculosis, however, there appears to be unanimity of opinion among authorities, there are certain points which require to be continually emphasized, and other points are now and then brought forward which possess a pleasing air of freshness.

A paper by Dr. David C. Murthu (*Practitioner*, June, 1916) provides an excellent example of the emphasis of salient features in the diet of consumptives and also supplies some useful hints with respect to particular kinds of food and modes of feeding. The writer is in complete accord with the great majority of English speaking physicians who have made a study, practical and theoretical, of the most scientific ways in which the tuberculous may be fed, that overfeeding is a mistake and in most instances is likely to do more harm than good. Forced feeding is not necessary in the early stages of the disease, and is not of much use in the late stages, when the stomach is too enfeebled to digest any food. As Murthu observes, the public are apt to forget that not the quantity of food, but the efficiency of the gastric organs to digest and assimilate, is the real criterion. Judgment as to the condition of a consumptive patient must not be based solely on weight, for the obese, flabby, tuberculous individual may and often is, so far as the progress of his malady is concerned, in a worse condition by far than the emaciated one. Rational feeding should be the motto in the treatment of the tuberculous, and not stuffing, and this is particularly true in the case of weak digestion, a very common failing, by the way, in persons afflicted with this disease. As a matter of fact, the secret of a successful diet depends more upon attention to economy in feeding than by giving way to extravagance. Nevertheless, while forced feeding should be tabooed, as a rule, there is a class of patients who must be induced to eat much more heartily than is their custom. Such persons, usually women, although possessed of normal powers of digestion and fairly good assimilative powers, have persuaded themselves that they cannot eat solid food. They are of a neurotic type and, by habitually denying themselves sufficient sustenance, have sunk into an aggravated neurotic state. It is incumbent in the treatment of such patients to use a certain amount of compulsion. A great lesson has been learned from experiments on foodstuffs, that their physical properties play a more important part in the process of metabolism than their actual chemical properties; the fresher the food the more easy and rapid the digestion, and the more nutritive its value. Murthu believes that milk to be nourishing and digestible should not be boiled, but given in its raw fresh state. This is obviously a matter of opinion regarding which it is impossible to say anything really definite.

Finally, it may be pointed out that worry, mental strain, and stress interfere with the physiological functions of the stomach and healthy metabolism. The consumptive, speaking generally, has a weak digestion, and therefore it is more essential to his well being than to that of the normal subject that he be free from anxiety and possess that contentment of mind which is said to be a continual feast. In arranging the diet of his patients the physician should take into consideration their mental condition and temperament, their habits of life and idiosyncrasies.

THE HEALING OF WOUNDS.

The cellular doctrine of Virchow is not only a beautiful theory, but a vital principle applicable to every day practice If we think of the human body in terms of cells rather than organs, we see at once

that any method of treatment which acts injuriously on the component cells will fail to benefit the organ. This is particularly true in the treatment of wounds. The old time antiseptic method applied to wounds interfered with union by first intention because although the germicide destroyed the bacteria, it also injured the cells. This is also true when the dressing is changed frequently and the wound disturbed. The disturbance induces traumatism in the cells and thus interferes with their normal functions. As pointed out by L. I. Omorokoff (*Roussky Vratch,* March 19, 1916) recent experiments on artificial cultivation of tissues demonstrated the interesting fact that when a bit of tissue is placed in plasma there is an initial period during which the cells remain inert. This is due to shock. At the end of that period, the length of which depends on the severity of the shock, the cells begin to grow. Precisely the same phenomenon takes place in wounds. The least shock is produced by a clean sharp instrument; conversely, the severest shock is induced in the case of contused, ragged wounds. The period of latency during which the cells are incapable of growth, will be shorter in the case of clean, incised wounds and longer in the contused and ragged ones. Manipulations of the latter, such as handling, cutting, or sewing, will only augment the shock to the cells, lowering their vitality and resistance to bacterial infections.

Doctor Omorokoff very properly makes the practical suggestion that in such cases the wound is best let alone for twenty-four hours, after the first simple dressing, when such surgical treatment as may be indicated is applied. He also calls attention to the fact that since certain salts or tissue extracts added to the plasma tend to stimulate the artificial growth of cells, it is possible that, by the application of certain solutions to the wounds, healing may be promoted. The beneficial results recently obtained by French surgeons in the treatment of wounds with a solution of magnesium chloride one to 12,000, thus finds a ready explanation.

DONATIONS FOR THE GOOD OF THE SERVICE.

We are pleased to note that many citizens realize their obligations in the present international crisis and have come forward with donations, which will help materially in promoting the efficiency of the military service. One of the most recent donations, that of two Ford touring cars, presented to the State by Mr. Thomas F. Vietor, of New York, for the service of the headquarters of the medical department, is most welcome and will add materially to the resources of this particular department. Mrs. Cornelius Vanderbilt has also presented to the State of New York a motor and seven ambulance trailers, which will be of great assistance to the medical corps. As announced in our last issue, through the liberality of various citizens equipment has been provided for thirteen Red Cross base hospitals, each of which is to be manned by details from hospitals in New York, Boston, Cleveland, Rochester, Baltimore, and Detroit. The Veterans' Association of the Seventh Regiment have contributed $35,000 toward the purchase of motors for the use of that command. Members of the Red Cross Association have ministered to the comfort of the National Guardsmen at various places on their way to the Mexican frontier. All this indicates a disposition on the part of the general public to render all the assistance possible to the Government and to the troops in the present emergency. Surely there is no better use for money than to make such contributions, particularly when intended to increase the efficiency of the medical department.

RURAL SANITATION.

In this day and generation it is no longer possible for a community to lead a life of isolation. No one aggregation of mankind is sufficient unto itself. It cannot exist without some intercourse with the outside world. As methods of transportation improve, one city becomes an actual neighbor of the next, in spite of the many miles that may separate them. We can now go in an hour distances that formerly took a day or longer.

For that reason a city cannot disregard the sanitary conditions that exist in more or less adjacent districts. As Surgeon General Rupert Blue (New York Medical Journal, June 17, 1916) pointed out in his address to the American Medical Association, rural sanitation is a matter of great importance to us all. Over fifty-three per cent. of the population of the United States dwell in communities of fewer than 2,500 inhabitants, in many instances under most insanitary conditions. In other words, forty-seven million people are affected directly by the health of the other fifty-three million.

One of the most important elements in this interrelation is that of food. City and the town dwellers depend upon the farmer for the greater part of their daily food supply, and as the demand is being made constantly for fresh materials, the transportation service improves and less time than ever intervenes between producer and consumer. This no doubt improves the quality of what we receive, but the very quickness of service makes the

menace to health so much more serious. The milk supply of a large city comes long distances, and the only way to insure its purity is to have proper sanitary conditions at the distant farms. One case of typhoid, or of septic sore throat, may start an epidemic among the distant consumers of that particular milk.

The only danger, however, is not from disease transmitted by foods. In the rural districts there is generally much laxity in regard to the quarantining of infectious diseases; the community is a small one, it is easy to avoid coming into contact with the patient, and indeed no one cares very much. To the dweller in the congested areas of a big city this uncontrolled case of smallpox or scarlet fever may be a matter of very serious moment. In the course of an hour or two the patient may have gone a hundred miles from his home and have become a bearer of widespread infection.

It is self evident that our efforts must be directed largely toward improving the sanitary conditions of the rural population. Malaria, typhoid fever, hookworm disease, all can be controlled if the people learn the necessity. Those of us who live in the cities must remember that no matter how good the laws may be, there will be trouble always unless we can remove distant centres of infection. Many a man has gone away for a summer vacation only to return home with typhoid fever or convalescing from it.

Rural sanitation is a distinct necessity for all, rural or urban, and must be sought after diligently in order to help in our constant warfare against disease.

Special Articles

MEDICAL ASPECTS OF THE MOBILIZATION OF THE NATIONAL GUARD.

The order mobilizing the New York division of the National Guard was promulgated by Major General O'Ryan shortly after midnight on Sunday, June 18th. Within twelve hours the medical officers without a single exception reported for duty as well as nearly the full quota of the enlisted men.

The rank and file of the National Guard has been kept a little above the minimum peace strength prescribed, which is about fifty per cent. of the war strength of the several units. The medical department is the sole exception, as it has been kept at about eighty-five per cent. of the full war strength. The equipment and medical supplies have also been kept at full war strength, with the exception of a few items of personal equipment for the enlisted men, such as clothing and shoes. This made it possible to mobilize the sanitary troops even more rapidly than the other branches of the service.

In addition to the sanitary troops in each regiment, there are attached to the New York division four ambulance companies and three field hospitals. All of these, with the exception of one of the field hospitals, which had only recently been organized, were completely equipped and supplied except for the draft animals. From June 20th to 27th the regiments were held in their respective armories with the exception of a part of the Twenty-second Regiment, the Sixty-ninth, the Third Ambulance Company, and the First Field Hospital, which were sent to Camp Beekman, and some artillery and cavalry commands which went into camp in Van Cortlandt Park.

From the moment the troops were assembled in their respective armories, the medical officers, assisted by members of the hospital corps, were busy day and night making a critical physical examination of every man in the guard, as well as of a large number of new recruits. These examinations were carried out under the supervision of a United States Army medical mustering officer.

On Tuesday, June 20th, at 6 p. m., about sixty hours after the promulgation of the order for mobilization, some 6,000 men had been examined, showing a very small proportion of rejections.

The excellent physical condition of the members of the guard thus shown is due to the more rigid enforcement during the last two years of the regulations regarding the examination for enlistment. Previous to that period there had been some laxity in the conduct of the examinations, which resulted in the admission of recruits who were not up to the physical standard. This situation appears to have been fairly well remedied if we may judge by the excellent showing made up to the present time. As only about one fourth of the National Guard of the State had been examined at that time, it remains to be seen whether the remainder of the organizations will make as good a record as those already passed upon.

The entire mobilization has been carried on without confusion, noise, or disorder. The showing made by the troops has been quite remarkable. This is particularly true of the men and officers of the medical department, upon whom, together with the supply officers, the larger share of the burden has fallen.

The medical department having been kept up to nearly full war strength, there are no vacancies among the commissioned officers of this department, and in fact there appears to be an excess for the particular duties required just now. A few enlisted men will have to be added to bring the sanitary units up to the full war strength, but it will be unnecessary to add untrained commissioned officers.

A depot battalion of sanitary troops has been left in charge of the armory of the First Field Hospital and the Third Field Ambulance to carry on recruiting, just as has been done at the armories of the line regiments which were ordered to the front.

The reports received from the troops en route and from those which have already arrived at the Mexican border, show that the men are in good condition. It remains to be seen how the northern men will stand the excessive heat of Texas.

THE NEW PRESIDENT OF THE AMERICAN MEDICAL ASSOCIATION.

Rupert Blue was born in Richmond County, N. C., May 30, 1867; his parents removed during his infancy to Marion, S. C. He was educated in the public and private schools, and attended the University of Virginia in 1889 and 1890; graduated from the University of Maryland with the degree of M. D. in 1892, and received the degree of Doctor of Science from that institution in 1908. He graduated from the London School of Tropical Medicine in 1910, and received the degrees of Doctor of Science from the University of Wisconsin and Doctor of Public Health from the University of Michigan in 1913.

Doctor Blue entered the Marine Hospital Service (now the U. S. Public Health Service) as an intern shortly after his graduation in medicine. In the following year, 1893, he passed the examination and was commissioned assistant surgeon in that service. He was promoted to the grade of passed assistant surgeon in 1897, and to the grade of surgeon in 1909. He was appointed surgeon general of the Public Health Service in January, 1912, and reappointed in January, 1916, and has served as an officer of the service at Cincinnati, Galveston, Charleston, S. C., Portland, Ore., Milwaukee, Genoa, Italy, New York, and Norfolk, Va.

RUPERT BLUE, M. D.,
Surgeon general, United States Public Health Service; president American Medical Association.

In 1903-04 Doctor Blue was in charge of plague eradicative operations in San Francisco. He served through the epidemic of yellow fever in New Orleans in 1905, and was director of sanitation of the Jamestown Exposition in 1907. In 1910 he represented the Public Health Service at the International Congress on Medicine and Hygiene at Buenos Aires, later making extensive surveys for the Government in South America and Europe.

In November, 1911, Doctor Blue was detailed as special sanitary adviser to the Governor and Territorial Board of Health of Hawaii in carrying out a program inaugurated for the improvement of sanitary conditions, with a view to minimizing the possibility of the introduction of yellow fever and plague into that territory after the opening of the Panama Canal. It was while engaged in this duty that he was appointed surgeon general, to succeed the late Walter Wyman.

Doctor Blue is a member of the American Medical Association; Fellow of the London Society of Tropical Medicine; member of the American Society of Tropical Medicine; the Royal Institute of Public Health; American Public Health Association; American Climatological Association; Association of Military Surgeons of the United States; National Committee for Mental Hygiene; National Mouth Hygiene Association; National Economic League; Fellow of the American College of Surgeons; member of the California Academy of Medicine, and the Medical Society of the City and County of San Francisco. He was elected president of the Association of Military Surgeons of the United States in 1915, and president of the American Medical Association in June, 1916.

According to an appreciative editorial article in the *Journal A. M. A.* for July 3, 1915, Doctor Blue was sent to Italy by the President when cholera threatened our shores in 1900. In 1905 he was second in command of measures taken in New Orleans and vicinity to eradicate yellow fever. In 1903 and again in 1907 he was placed in charge of plague eradicative measures in California, and handled a difficult situation with the result, not only that the disease was controlled, but also that all interests in the State were harmonized. The last mentioned is perhaps the most important single work he has performed, and during its conduct he advanced and proved the principle that rat proofing is the essential means necessary to prevent plague in urban communities. As a result of the enforcement of rat proofing, he has demonstrated that the eradication of plague is entirely practicable, and, in consequence, that cities may be kept free from the disease.

Perhaps the most significant achievement of Doctor Blue's career, however, has been the remarkable development of public health work under his direction, especially as relates to scientific research. Public health education by the Federal Government is important, but the conduct of investigations along broad lines, and continuously followed, is by all odds the most important function of the Federal Government in matters affecting the public health. This he has encouraged, as is evidenced by the many lines of new work undertaken in the recent past. Some of this work has been done in cooperation with other branches of the Government, and a cordial system of cooperation seems to be one of the means taken now to advance public health work.

News Items

Personal.—Dr. Rosalie Slaughter Morton, of New York, will sail for Europe on July 8th, to aid in relief work in Serbia.

The degree of doctor of science was conferred upon Dr. Ludwig Hektoen, director of the Memorial Institute for Infectious Diseases, Chicago, by the University of Wisconsin, at the commencement held on June 21st.

Septic Sore Throat in Bridgeport, Conn.—According to press dispatches more than 200 cases of septic sore throat have been reported in Bridgeport, Conn., during the two weeks ending July 3d, with fifty deaths. It is said that the outbreak is due to infected milk.

Tuberculosis Research at Johns Hopkins Hospital.—Announcement is made of a gift of $95,000 to Johns Hopkins Hospital by Dr. Kenneth Dows, of New York, to be devoted to the investigation of tuberculosis and the better teaching of physicians and students in the recognition and treatment of the disease.

Anonymous Gift to Babies' Hospital in Philadelphia.—The Babies' Hospital of Philadelphia has received a gift of $50,000 to be used for the erection of a new and modern building in Philadelphia. A woman, who refuses to allow her name to be published, has made the gift. Several sites are being considered for the new institution, and as soon as one can be decided upon, the work of construction will be begun.

Kansas Medical Society.—At the annual meeting of the society, held recently in Topeka, Dr. J. W. May, of Kansas City, was elected president, and other officers were elected as follows: Dr. M. T. Sudler, of Lawrence, first vice-presdent; Dr. Alfred O'Donnell, of Ellsworth, second vice-president; Dr. T. A. Jones, of Hutchinson, third vice-president; Dr. Charles S. Huffman, of Columbus, secretary, and Dr. L. H. Munn, of Topeka, treasurer. Next year's meeting will be held in Salina.

The New Queensboro Hospital.—The first of the group of buildings of the new Queensboro Hospital, which is conducted by the department of health, was opened on June 30th. It is said that the new building embodies the most modern ideas regarding the handling of contagious diseases. The hospital is under the supervision of Dr. Robert J. Wilson, director of the Bureau of Hospitals, and Dr. Charles T. Sharp will be resident physician in charge. The hospital has accommodations for eighty patients, and the cost of the building was $76,000.

Training Camps for Doctors.—Major General Leonard Wood, commanding the Eastern Department of the United States Army, announces that two training camps for medical men will be held in connection with the regular Plattsburg military training camp this month. The first camp will open on Wednesday, July 12th, and the second on July 24th. The course of instruction will be the same at both camps, and will emphasize camp sanitation and military hygiene. The camps will be commanded by medical officers of the regular army. Physicians desiring to attend one or both of these camps should communicate immediately with the Military Training Camps Association, 31 Nassau Street, New York, where enlistment blanks will be furnished.

The Collection and Distribution of Military Relief Supplies.—Major General Arthur Murray, U. S. A., acting chairman of the central committee of the American Red Cross Society, has issued supplementary instructions for the collecting and distributing of military relief supplies. Six intermediate depots, where supplies should be sent to be sorted and classified, have been named in the following districts: New York, Cincinnati, Chicago, Kansas City, Denver, and San Francisco. Additional distributing depots, from which final distribution of supplies will be made to the troops at the front, have been designated at Douglas, Ariz., El Paso, Texas, and San Antonio, Texas.

Measures Taken to Protect Up State Children from Infantile Paralysis.—Defensive warfare to protect the thousands of up State children against the epidemic of infantile paralysis now covering greater New York has been undertaken by Commissioner Hermann M. Biggs of the State Department of Health. Health officers of six counties have been warned against the epidemic and personal letters to every physician in the State are to follow. Local health officers are instructed to report by telegraph every suspected case of infantile paralysis and enforce the strictest quarantine of the patient. The health officers are also urged to give the widest possible publicity to the order, and in the case of an epidemic to issue special bulletins so that the people may be informed of the dangers.

The Alumni Association of Jefferson Medical College elected the following officers at the annual meeting held in Philadelphia recently: President, Dr. J. Coles Brick; first vice-president, Dr. E. Q. Thornton; second vice-president, Dr. P. Brooke Bland; treasurer, Dr. Warren B. Davis; secretary, Dr. H. K. Mohler.

Yale University to Have a Board of Health.—It has been decided to establish at Yale University a university board of health which will have charge of the physical and medical examination of all students at the university, the supervision of all men taking part in athletics, the inspection of all dormitories, recitation buildings, assembly halls, etc. This board consists of the following members: Dr. Frederick S. Jones, dean of the college; Dr. Russell H. Chittenden, director of the Sheffield Scientific School; Dr. George A. Blumer, dean of the medical school; the professor of public health, the professor of bacteriology and hygiene, the treasurer of the university, the director of the gymnasium, and the chairman of the athletic association. Dr. James C. Greenway has been appointed university health officer for next year.

A Conference of the Sanitary Supervisors of the State was held in New York last week. Twelve sanitary supervisors, representing the several districts into which New York State is divided for purposes of sanitary work, were at the conference. Three days were devoted to intensive study under the guidance of members of the State department staff and prominent physicians and surgeons of New York city. During the first day they visited a modern pasteurization plant. Several hours were spent at the Rockefeller Institute, and the rest of the day was spent in the research laboratory of the New York department of health. The study of tuberculosis, infant welfare stations, and communicable diseases took up the second day of the conference. The Vanderbilt Clinic was at the disposal of the physicians and some time was also spent at the Willard Parker Hospital. During the last day of the conference the health officials visited the diagnostic laboratory of the city health department and heard lectures on administrative control, supervision of foods and milk, and visiting nursing. The supervisors also inspected the quarantine station at Staten Island and the tuberculosis sanitarium at Otisville. The conference was concluded with lectures at the New York office of the State Health Department.

Infantile Paralysis in New York.—A report issued by the department of health on Wednesday, July 5th, shows that the epidemic of infantile paralysis is still on the increase. In Brooklyn 157 cases were reported during the preceding forty-eight hours, and eighteen new cases in Manhattan during the preceding twenty-four hours. The death toll continues high. There were 22 deaths in the 48 hours from Saturday noon, July 1st, to Monday noon, July 3d. In the 24 hours following, ending July 4th noon, 26 deaths were reported; all but three of these were from Brooklyn. In the past 24 hours 7 deaths had been reported. This makes over 150 deaths in approximately 600 cases thus far reported, a mortality of 25 per cent. This is a much greater mortality than has heretofore been experienced in epidemics of this disease.

The department of health has enlisted the services of two large life insurance companies to aid in the distribution of warning leaflets. A special staff of experts to care for the patients in the Kingston Avenue Hospital has been organized with Dr. Lewis C. Ager as chief. Associated with him are Dr. Eugene F. Dalton, Dr. Murray B. Gordon, Dr. Judson P. Pendleton, Dr. Philip W. T. Moxom, Dr. Robert O. Brockway, a nerve specialist, Dr. Walter Truslow, an orthopedic surgeon, and Dr. Alexander Sophian, a laboratory expert.

The field staff, working under Doctor Blatteiss, consists of thirteen physicians, thirty nurses, and twenty sanitary inspectors; twenty-five men will inspect all places where food is handled or sold. At the request of Commissioner Emerson, the Department of Licenses has notified all motion picture theatres in the city not to admit children under sixteen years of age from July 5th until such time as the board of health declares this health menace at an end.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Twenty-seventh Communication.

IPECACUANHA.

Although the hoary custom of "puking" patients has fortunately passed into desuetude, the occasional necessity for provoking emesis makes it desirable to keep at hand some fairly trustworthy drug; and no oral emetic is so satisfactory, in both positive and negative qualities, as ipecac, a drug which acts chiefly on the mucous membrane of the stomach, and which when retained, is absorbed but slowly.

On the central nervous system no direct action is determinable when ipecac is administered to man. In frogs there is produced a central paralysis, through means not clearly understood. In rabbits there seems to be a depression of the motor side of the spinal cord. In man, following large doses, there is produced a feeling of marked lassitude and muscular weakness, due, it is believed, to a reflex exhaustion arising from the prolonged nausea and vomiting rather than to any immediate effects of the drug itself.

The heart is usually somewhat slowed, probably through reflexes from the stomach. Following large doses there is a considerable fall in blood pressure, seemingly due to splanchnic relaxation; but whether the effect is centric or reflex is uncertain, though present opinion favors the latter view. Researches are needed on blood pressure when ipecac is administered for amebiasis.

The mucous membrane of the stomach and bowel is considerably irritated by ipecac, though it is not clear what may be the exact nature of that form of irritation that results in emesis. There is greater activity of both the salivary and gastrointestinal glands, but possibly less from the drug than as the obscure but fairly uniform accompaniments of nausea. The bronchial and pharyngeal glands also show increased activity; this would seem to be due to a local effect following absorption, a view somewhat supported by the fact that in rabbits ipecac sometimes produces a pulmonary edema.

In some cases of nausea, due to a depressed and atonic condition of the mucous membrane of the stomach, a small dose of ipecac (eight mg. of the powder) often affords complete relief, probably by bringing the tissues up to a more nearly normal condition. Somewhat larger doses (sixty mg. of the powder, or one c. c. of the syrup) seem to be mildly expectorant, except in some sensitive subjects who may become nauseated. The emetic dose for an adult is fifteen c. c. of the syrup, often best administered in a large quantity of tepid water. Emesis is often greatly facilitated by this drug, while the addition of water tends to make the process more efficient; and if vomiting is inevitable, the patient profoundly wishes such a degree of expulsive efficiency as to insure a speedy and complete consummation.

Ipecac is inimical to some protozoan forms of life, and to this end has been used with gratifying results in amebic dysentery. In this treatment large doses are essential (two to four grams of the powder), and must be so administered as not to induce emesis. Formerly this result was obtained by depressing the patient's reflexes with laudanum, but now the drug is usually administered in capsules or casings soluble in the alkaline secretions of the duodenum, but not in the acid secretions of the stomach. How much systemic reaction occurs in this treatment does not appear, few analytical investigations having been made; absorbability may be so slow as to give but indefinite reactions.

One of the active principles of ipecacuanha, emetine, has lately been successfully employed in the local treatment of pyorrhœa alveolaris, but the experimental work is not yet sufficiently advanced to justify conclusive statements.

Ether-Oil Anesthesia.—A. K. Evropin (*Rousky Vratch,* March 19, 1916) employed Gwathmey's method of ether-oil rectal anesthesia in a number of operations performed on soldiers in the war zone. He found the method simple, not to require a trained anesthetist, and at the same time efficacious. That the anesthetic can be administered to the patient in bed, before he is brought into the operating room, not only allays the anxiety of the patient, but enables the surgeon to perform a larger number of operations. The dose of ether by this method is more exact than is the case with inhalation, and much safer. In operations on the face or respiratory passages this method is indispensable. The ether was detected in the breath three to four minutes after the injection, and in ten minutes anesthesia began, reaching its height in thirty to thirty-five minutes. The sleep was natural, lasted about three hours, and was followed by awakening, which was not accompanied by headache, nausea, vomiting, or any of the usual disturbances.—O. A. Revidtsova and La. B. Dombrovska also publish their results. In their experience a stage of excitement, particularly marked in alcoholics, developed in ten to twenty minutes. This they diminished to a minimum by administering fifteen to twenty c. c. of ether by inhalation as soon as excitement appeared. Narcosis appeared in forty to fifty minutes and lasted for two to four hours. Vomiting during the operation was observed in three cases, and in fifteen per cent. when the patients came out of the anesthetic. The authors note the advantages of this method in operations on the head and face, in pulmonary complications, and in the absence of an experienced anesthetist. On the other hand, the introduction of a

considerable amount of ether at one time presents the grave danger of individual intolerance. Should such a condition present itself, the anesthetic cannot be withdrawn. Deaths from this method have been reported. Moreover, while the method itself is simple enough, the washing out of the remaining ether-oil from the rectum is bothersome and requires extra help. The authors urge caution.—G. A. Garnak contributes a paper on the subject, reviewing historical data and giving his own experience. It appears that the method of introducing ether vapor through the rectum was first suggested by the Russian surgeon, Pirogoff, in 1887, and was then taken up by other surgeons who, however, found it unsatisfactory, owing to the irritation of the intestinal mucosa produced by the ether. The Gwathmey technic eliminates this objection. The author employed this method in hospital practice with most satisfactory results. By lowering the vessel containing the ether-oil, when needed, he not only relieves the distention of the colon with ether vapor, but is also in a position to allow the anesthetic to flow back into the container should it become necessary for any reason to stop the anesthesia. The only objection was the prolonged narcosis after the operation, lasting four hours. The advantages are the absence of fear on the part of the patient, the more complete muscular relaxation, and the ease with which anesthesia can be regulated.

Treatment of Chancroid.—F. Balzer (*Paris médical,* May 6, 1916) states that the application of water at a temperature of 45° C. or above, or prolonged irrigations with hot 0.25 to one in 1,000 potassium permanganate solution often give excellent results in chancroids. The same is true of the use of the thermocautery. These methods are all inferior, however, to the use of a stream of heated air, supplied by one of the various forms of apparatus adapted to the purpose. Vaccines prepared from the Ducrey organism have not as yet given convincing results. Various pyogenic organisms are often present in combination with it and in chronic chancroids and buboes with a phagedenic tendency the polyvalent serum of Leclainche and Vallée may be used externally with advantage. Balzer employed it recently in a case of multiple lesions of the glands and prepuce, with markedly beneficial effects in four days. Further treatment consists in cauterization two or three times with ten per cent. zinc chloride solution, with ten per cent. phenol solution in alcohol, or with calcium carbide. The latter should be applied in a thin layer after careful cleansing of the chancroid with water, and covered with a little absorbent cotton. At the next dressing the carbide is replaced with iodoform, europhen, or aristol, which may be renewed several times daily. Sometimes it removes the virulence of the lesion after a single application; if not, it should be used again after forty-eight hours. As a result of its action the lesion loses its yellowish color and irregular base and becomes reddish and healthy in appearance. The carbide is advantageous in that its action is more easily limited, though no less certain, than that of zinc chloride. It may also be used in lupus. As a substitute for the malodorous iodoform, Balzer recommends the use of a freshly prepared zinc-silver paste, made by mixing 100 grams of zinc filings with twenty c. c. of one per cent. silver nitrate solution. Nitrate of zinc and reduced silver are formed, which act strongly on the soft chancre and remove its virulence after a few applications. If dried at 30° to 50° C. the paste yields a powder which can be kept in a tightly closed container and later used as required. After the virulence of the lesion has been destroyed, the zinc-silver paste further completes its disinfection. Where the caustic action persists a double amount of zinc filings may be used, or the preparation may be abandoned and replaced with aristol or by the following ointment, which is especially useful when the already sterilized chancroid has begun to granulate:

℞ Argenti nitratis, ... 1 gram;
Balsami peruviani, ...)
Adipis lanæ hydrosi,)..... āā 10 grams;
Petrolati albi, ...9. s. ad 100 grams.
Fiat unguentum.

This ointment should be used continuously until repair is complete.

Prophylactic Inoculation against Typhoid and Cholera.—Ferdinand Hueppe (*Berlin. klin. Woch.,* December 13, 1915) has encountered failures in both typhoid and cholera inoculations and suggests some explanations for these occurrences. Among the more important are that there are many different strains of each of these organisms and it is possible that immunity to one strain may not include immunity to another; or that a strain may be encountered which is sufficiently virulent to overcome an artificially induced partial immunity. When inoculation has to be practised on a large scale the preparation of the vaccines is often careless and rough methods are employed for estimating their bacterial contents, so that the doses given may be too small in many cases. Finally, the subcutaneous method of administration may not lead to an efficient local immunity in the tissues which constitute the usual portals of entry for the infection.

Materials Available for Thyroid Feeding.—John Rogers (*N. Y. State Jour. Med.,* May, 1916) remarks that owing to variability in activity of the commercial thyroid preparations and their crudity, experiments were begun several years ago to determine more accurately something definite about the materials of therapeutic value which could be obtained from the thyroid gland. It was found that the active substances present were soluble in water and could readily be extracted from the gland by maceration of the fresh, hashed tissue in saline and expression. Since autolysis was found to alter or more or less destroy the active substance, fresh glands only should be used. By a process described in detail it was possible to separate two chief portions of the extract—the one containing the nucleoproteins, some of the coagulable proteins and the globulins, the other a noncoagulable soluble residue. Both portions were found to have physiological actions. The first portion could be dried and made into tablet triturates with lactose, the second may be used in the form of an aqueous solution. The tablet preparation of the proteins was found to yield most satisfactory results in cases of myxedema, often proving effective where

the previous feeding of the whole gland had been without influence. The second portion of the extract when given intravenously to dogs was found to cause marked fall of blood pressure, deepened respiration, but no increase in the heart rate, and to be extremely active in these respects, although large doses failed to kill the animals. The preparation was used in man in doses of three to twenty drops from two to five times daily, alone or in combination with the thyroid proteins, and often proved markedly beneficial in the mixed cases of hypothyroidism and hyperthyroidism, in true hyperthyroidism and in some cases of hypothyroidism when given with the proteins. Case histories illustrate the results obtained from the use of these two new thyroid extracts.

Gerontal Constipation and Its Treatment.—W. Ainslie Hollis (*Brit. Med. Jour.*, May 13, 1916) states that the general causes of this form of constipation include pressure by an enlarged prostate, dryness of the intestinal mucosa and contents, overeating and dietetic indiscretions. Drugs can be no more than palliative in the treatment of this condition, but serve a useful end in preventing colic blocking. The most satisfactory remedy is the aromatic fluidextract of cascara, given in full doses whenever there is a diminution in the quantity or change in the consistence of the intestinal evacuations. The circulation should be looked after and small doses of the tincture of strophanthus, given in water with a few grains of sodium bicarbonate, fill this need admirably. The reduction of meats, thorough mastication of all food, and the free use of fruits are the only needed dietetic modifications. Lastly hemorrhoids, anal fissures, rectal prolapse, etc., must be cured before a satisfactory result can be obtained.

Etiology and Treatment of Arthritis.—Estill D. Holland (*Southern Medical Journal*, June, 1916), finds that sixty-five per cent. of the cases of arthritis deformans give a history of prior susceptibility to the ordinary pus organisms, such as streptococcus and staphylococcus, or have suffered from some acute infection, such as a cold, grippe, or infected teeth or gums shortly before the attack of arthritis. Such cases he treats with a mixed vaccine consisting of streptococci, 200,000,000, staphylococci, 800,000,000, and Micrococcus catarrhalis, 100,000,000 to the c. c., which is a full dose. This he gives at varying intervals, depending on the susceptibility of the patient, as shown by the reaction. He asserts that the results obtained where they are used are usually better and more permanent than in cases where they are not used.—In the discussion of this paper J. W. Torbett called attention to the fact that other methods of treatment should not be stopped. Diet is an important factor, and so is increase of elimination and the proper use of hot and cold applications. An ingrowing toenail is one source of infection, and the alimentary tract may be another requiring treatment.—E. H. Martin said that he had seen some good results in Doctor Holland's cases, but had failed to get them in his own. He has obtained some results from assisting elimination by means of high frequency currents applied to the spine and the multiplex over the abdomen, and by high colonic flushing, using from two to four gallons of water, following this up with an enema of quinine solution. Another measure that gave relief was faradic gymnastics and artificial exercise, which induce a heavy sweat and aid elimination.

Influenza.—A. R. Bond (*Journal Florida Medical Association*, May, 1916) states that owing to the infectious nature of this disease the measures for the prevention of its spread are very important. The same precautions should be adopted with regard to coughing, spitting and sneezing as are used in tuberculosis. In addition the nose and pharynx should be cleansed frequently by sprays and gargles of equal parts of peroxide and water, a ten to twenty-five per cent. solution of alcohol or Dobell's solution. The treatment is symptomatic and hygienic, the latter including enforced, prolonged rest in bed until convalescence has been well established and the provision of a suitable liquid diet. The acute stage should be cared for by the administration of six to eight quarter grain doses of calomel and soda at half hour intervals, followed by a saline. Ice caps, cold applications to the head and alcohol rubs are comforting and the following prescription should be given every three hours for two to three days:

℞ Acetphenetidini, ...grs. ij;
Phenylis salicylatis, ...grs. ij;
Pulveris ipecacuhanæ et opii, }
Caffeine citratis, ... } .....āā gr. j.

Tonics and stimulants, in the form specially of strychnine and quinine in small doses should always be given as soon as depression begins to be evident. The use of alcohol, except for patients long accustomed to their frequent daily drinks, is absolutely contraindicated.

Ulcer of the Stomach.—D. J. Hyman (*Medical Review of Reviews*, June, 1916) believes that many gastric ulcers may be cured without operation, and that every ulcer should be treated medically first, but if this treatment proves unsuccessful the patient should be handed over to the surgeon, on account of frequent transformation into carcinoma. Duodenal ulcers are not so prone to malignant degeneration, and watchful waiting may be practised a little longer, although one should bear in mind always the dangers of perforation, hemorrhage and adhesions. Treatment of ulcers demands a thorough knowledge of the pathology of the lesion, its location and complications, as well as a proper appreciation of the value, indications and limitations of drugs. The most useful are sodium bicarbonate, the bismuth salts, magnesium salts, Carlsbad salts, Saratoga water, olive oil, liquid petrolatum, extract of belladonna and atropine, which are used to neutralize or inhibit the secretion of hydrochloric acid, or to act as a protective coating to the ulcer. The most striking and immediate symptomatic improvement follows the administration of large doses of bicarbonate of sodium. Twenty to 100 grains may be given three or four times a day, from one to four hours after meals. Excellent results are obtained also

from the bismuth salts, but the great objection to them is their obstinate constipating effect. Alkaline waters are especially useful at the spas. As regards diet each case must be studied individually, and care must be taken that no coarse or indigestible food is given. In some it may be largely carbohydrate, in another rather liberaliy albuminous. If medical treatment has failed after a fair trial surgical treatment should be instituted.

Treatment of Chronic Colon Pyelitis by Pelvic Lavage.—Herman Louis Kretschmer and Fred W. Gaarde (*Journal A. M. A.*, June 24, 1916) report that this chronic form of pyelitis is notoriously resistant to treatment by medical measures, but excellent results have been obtained by the authors with a combination of internal medication and local lavage. First a week is devoted to the administration of one teaspoonful of sodium bicarbonate three times daily to alkalinize the urine. This is then stopped and for one week acid sodium phosphate given to acidify the urine. During this week from thirty to seventy grains daily of hexamethylenamine are administered. These weekly periods are alternated as often as needed. Simultaneously the infected renal pelvis is irrigated through a small ureteral catheter with a one per cent. silver nitrate solution. Treatment should be continued until repeated cultures of ureteral specimens of urine are sterile. Recurrence was probable if treatment was not also directed to bladder infection, if present, or to infection in any portion of the pelvis which might lead to reinfection of the renal pelvis. In a few instances a single ureteral irrigation sufficed, but in others several were required. A total of about five to ten c. c. of the solution was used for each irrigation and was introduced very slowly and under low pressure. The irrigations were repeated at intervals of five to six days.

Peripheral Neuritis in Jamaica.—C. R. Edwards in the *Journal of Tropical Medicine and Hygiene* for March 1, 1916, describes this condition as very common among the native population of the island. It occurs oftenest in young adults. It is of slow progress, terminating fatally in some instances in about twelve years, while in others it lasts until old age. In some cases the victim wakes up one morning to find that he has lost the use of both legs; or again the symptoms come on gradually. Sight and hearing are greatly affected, and severe girdling and lightning pains are always experienced. Wasting, a parchmentlike skin, and symptoms identical with those of tabes dorsalis, but without abolition of the pupillary light reflex, are also typical manifestations. The treatment consists in feeding up and relieving the pains by rubbing the muscles with liniments. Drugs are useless. Under the feeding up treatment, motor power may be quickly regained in the young, but in old cases results are much less satisfactory. In all cases the conditions of life were bad, and the food was often scanty and deficient in nitrogen. At autopsy, degeneration of nerve cells in the posterior and lateral columns of the spinal cord was present, and in some isolated patches in the cerebellum and the optic and auditory nuclei. No causative microorganism was found, and the condition is believed to be probably a food disease. It is held to be quite distinct from beriberi or pellagra.

Therapeutic Possibilities of Antitetanus Serum.—H. E. Robertson (*American Journal of the Medical Sciences*, June, 1916), proposes that every case in which symptoms of tetanus appear should be treated at once with an intravenous injection of 3,000 units of antitetanus serum. He emphasizes particularly the "at once." Even the saving of minutes of time may mean the difference between life and death. He does not believe that the lives of all, or even of a large proportion of the patients with tetanus can be saved in this or in any other way, but that this is the best available means to save them. The size of the dose is relatively unimportant, and repeated injections are of little or no value.

Treatment of Ecthyma and Other Local, Superficial Suppurative Lesions in Military Practice.—L. Chastanet (*Presse médicale*, May 11, 1916) refers to the sores met with frequently on the lower limbs of soldiers engaged in trench warfare, which have proved refractory to ordinary therapeutic measures. The author first removes the crusts with sterile moist cotton pledgets, cauterizes the lesion deeply with silver nitrate, and applies a sterile wet dressing. Cauterization is continued until the previously blackish tissues become reddish, when, after a last cauterization of the entire lesion, including its margins, one in ten tincture of iodine is freely applied. The surface is then tamponed with slightly moistened cotton and a dry sterile compress is applied. If the lesion is not dry the next day, the procedure is repeated. After it has dried, no further dressing is required, healing taking place under the adherent coating formed by the drugs.

Effect of Mineral Alkalies and Other Drugs on the Uric Acid Solvent Power of the Urine.—H. D. Haskins (*Archives of Internal Medicine*, March, 1916) reports an investigation of the uric acid solvent power of piperazin, lysidin, and various alkalies, conducted in human subjects. The solvent power was estimated by determining the amount of uric acid taken up when the urine from subjects to whom the various drugs had been administered was shaken with pure uric acid for twenty minutes. It was found that piperazin in one to four gram doses can cause the urine to dissolve an increased amount of uric acid; this effect is most marked if sodium citrate or bicarbonate is also given and if diuresis is avoided. Lysidin, though it can also act as a uric acid solvent, is not of practical value because of the large doses necessary. Lithium carbonate was likewise effective, but proved unsafe, causing toxic symptoms in moderate doses. Sodium citrate and bicarbonate, on the other hand, proved to be safe as well as trustworthy urid acid solvents when given in such doses as to maintain an alkaline reaction of the urine. The doses of bicarbonate and citrate ranged from two to four grams. The greatest total solvent action would probably be secured by combining diuresis from copious water drinking with alkalinization of the urine by sodium bicarbonate or

citrate. Whenever normal urine becomes alkaline and contains many metal ions as a result of the diet, it likewise shows a marked uric acid solvent action.

Medical Treatment of Gastric and Duodenal Ulcer.—Fenton B. Turck (*Medical Record*, June 24, 1916) requires rest in bed for two or preferably three weeks with a preliminary fast of three days when only water is allowed. On the fourth day 800 c. c. of cornstarch gruel is given in one meal and afterwards two meals daily are given with increasing amounts of rice, steamed vegetables and hydrolyzed meat. When meat is given early in the second week it is soaked in cold water for twelve hours and the juice is expressed and discarded to avoid hyperchlorhydria; the meat pulp is placed in boiling water and steamed for one or two hours until jellied. Turck also uses continuous drainage of fluid from the stomach by a tube filter devised by him in 1894. Gastric lavage encourages atony, although washing with silver nitrate is useful where there is high acidity. Vaccines are of service and blood serum checks hemorrhage. As to drugs, atropine is useful to control hypersecretion, while bismuth, bran, slippery elm, Irish moss, kaolin and other materials are used to mechanically remove microorganisms from the mucous membrane of the stomach.

X Rays and Radium in Enlarged Lymphatic Glands.—Robert Knox (*Archives of Radiology and Electrotherapy*, June, 1916) states that the principal type of radiation employed in these cases has been a moderately hard x ray, and when radium was used the gamma ray with a filtration of three or four mm. of lead or one or two mm. of platinum when applied over the skin surface. Enlarged glands respond to radiation in the following order: Simple inflammatory glands are quickly influenced by a few exposures; the treatment is not applicable to enlarged glands where pus formation has commenced; 2, lymphadenomatous glands are less quickly acted upon, but almost invariably diminished in size soon after a number of exposures of hard radiations; 3, tuberculous glands are not readily affected: they require a large number of exposures at short intervals to induce retrogressive changes, but ultimately these also slowly respond to radiation treatment; 4, malignant glands are also influenced; sarcomata respond much more readily than carcinomata. They may disappear but are apt to recur. Carcinomatous glands rarely disappear under treatment, but they may diminish much in size. In enlarged glands due to a mixed infection the response to treatment may be irregular, some glands subsiding rapidly while others respond slowly. The x ray becomes of value as a means of diagnosis if its effect on the glands is noted. In order to render the method practical it would be necessary to standardize the exposure. In estimating the reaction to radiations the biological factor is of some importance, and as this is not constant, varying in different individuals and in the same individual at different times, it is a disturbing element in estimations. Drugs such as iron, arsenic and mercury also affect the response to radiations. When a group of enlarged glands has been reduced to a moderate or small size the expediency of operation should be raised. It is probably better to remove the glands thoroughly and, in a number of cases, postoperative treatment is advisable. In malignant enlargement of the lymphatic glands no case should be treated unless a surgeon has deemed it unwise to operate.

Treatment of Gas Gangrene.—G. Campora (*Gazzetta degli ospedali e delle cliniche*, May 28, 1916) advises destruction of the primary focus, free incision of the wound, disinfection with hydrogen peroxide, permanganate of potassium or iodoform and ether, followed by a pursuit of the infection along its paths of diffusion and reaction and free incisions combined with irrigations of peroxide and drainage with gauze moistened therewith.

Treatment of Septic Wounds with Salicylic Acid.—Anderson, Chambers, and Lacey (*Lancet*, June 3, 1916) report on 1,000 cases in most of which salicylic acid irrigations were used. A saturated solution of the acid was made in alcohol, and of this two to three drams were added to a pint of saline used as an irrigation, thus depositing the crystals over every part of the wound. A paste made with one gram of acid to nine c. c. saline solution was frequently used for cut surfaces of long bones in septic amputations. Where it was desired to use a weaker preparation over a long period two to four per cent. salicylic acid in gelatin was used. Salicylic acid seemed to save cases where other methods failed.

Parasites in Stools of 1,305 Dysenteric Patients.—H. B. Eantham (*Lancet*, June 10, 1916), without examining for bacteria, reports that these cases showed 471 with Lamblia intestinalis infection, 211 with Entamœba coli, and 198 with Blastomyces enterocola.

Treatment of Sacroiliac Arthritis.—W. H. Deaderick (*Lancet Clinic*, May 6, 1916) points out that, like most other forms of arthritis, sacroiliac disturbance is usually secondary to a source of infection elsewhere in the body, e. g., the prostate, or the gums. The first aim in the treatment should be, therefore, to locate and, if possible, remove the primary focus. Vaccines or prostatic massage may be necessary or, as in a case the author reports, the administration of emetine for alveolar pyorrhea. In the case referred to, that of a man of thirty-four years, chills and fever had been experienced almost every summer, about a year before the beginning of the treatment he began to have "rheumatism" of the right hip, with backache and pain referred down the leg, worse at night, headache, and "cold shakes." Marked sacroiliac tenderness was noted, together with pronounced pyorrhea. The patient was given one half grain of emetine by injection daily for six days, with wine of ipecac as a mouth wash, baths in radioactive water, and hot wet packs to the back and legs. In nine days he was able to walk with but one crutch, a week later with a stick alone, and soon after was at work. Strapping the joint with wide strips of zinc oxide adhesive plaster is often indicated, especially where the joint is relaxed as well as inflamed. Massage is grateful to some patients after acute symptoms have disappeared.

Miscellany from Home and Foreign Journals

Radiography in the Diagnosis of Diseases of the Accessory Nasal Sinuses.—H. Martin Berry (*Archives of Radiology and Electrotherapy,* June, 1916) finds that in most cases all the desired information can be obtained from two plates—one taken anteroposteriorly, and the other laterally. For a lateral view the patient may either sit upright or lie on the side. The plate should be at right angles to the central ray, which should traverse the head in a strictly transverse plane. The extent of the frontal sinuses and their anteroposterior depth can be determined by combining the information obtained from the anteroposterior and lateral views. The variations in the frontal sinuses are noteworthy. They develop as extensions of the anterior ethmoid cells. A normal frontal sinus has been defined as extending to about the junction of the inner and middle thirds of the supraciliary ridge, rising vertically about twenty to twenty-two mm. above the nasion. A point to be noted in frontal sinuses is the presence or absence of septa, complete or incomplete, causing loculation of the cavity. The depth of the sinus is of importance only if an operation for its obliteration is contemplated.

Variations in Glycuronuria in Liver Affections.—H. Roger (*Presse médicale,* May 18, 1916) calls attention to the importance of glycuronic acid in the system in the detoxication of various alcohols, aldehydes, phenols, ketones, anilin, acetanilide, naphthol, camphor, etc., and points to the diagnostic and prognostic value of determinations of this acid in the urine in various hepatic and other disease conditions. He has devised the following test for glycuronic acid: In a centrifuge tube are placed five c. c. of urine, 0 2 gram of ammonia, two c. c. of commercial lead subacetate solution, and enough distilled water containing one per cent. of ammonia to fill the tube. The resulting heavy precipitate is centrifugated and washed with the dilute ammonia three times, then mixed with five c. c. of distilled water in a test tube, and 0.5 c. c. of a one per cent. alcoholic solution of naphthoresorcin. To remove all the precipitate remaining in the centrifuge tube five c. c. of pure hydrochloric acid are used. The product is then heated on a water bath at boiling temperature for fifteen minutes, cooled under a stream of cold water and shaken up with five c. c. of ether. When the urine contains no glycuronic acid a yellow or sightly reddish solution is seen; when it does, a violet color. Normal urine contains 0.04 gram per litre of glycuronic acid, combined with phenol, indol, and, perhaps, skatol. Variations in the glycuronic content of the urine yield precise information on the function of the liver and its content of glycogen. Fasting or a milk diet reduces the glycuronuria. In case of doubt administration of 0.5 gram of camphor in a cachet, together with some starchy or sugar bearing food, will yield a strongly positive reaction if the hepatic functions are unimpaired. In numerous cases of hepatic cirrhosis Roger found the test becoming less and less strongly positive as the disease process advanced, and completely negative shortly before death. In obstructive jaundice, on the other hand, the test was always more strongly positive than normal, owing to increase of putrefactive products in the intestine requiring detoxication. In catarrhal jaundice the test was at first normal or hypernormal, but showed a marked diminution in the posticteric period. The test has been applied also in the study of pneumonia cases, cases of pregnancy, and in athrepsic newborn infants, and is available wherever the hepatic functions are in question.

An Easy and Rapid Method for the Widal Test.—Alfred C. Coles (*Brit. Med. Jour.,* May 13, 1916). With a grease pencil or some wax two ordinary slides should be divided across their centres by a heavy line. On one end of each spread a thin film of the suspected blood and on the other ends a film of normal blood, from one who neither has had typhoid, nor has been prophylactically inoculated. Allow the films to dry. With a platinum loop spread a drop of an emulsion of typhoid culture evenly over each half of both slides, sterilizing the loop before passing from one to the other half in each case. Fit cover glasses to each half of one slide so that they do not touch at the waxed line, and examine both halves under the moderately low power. Leave the remaining slide, without cover glasses, under a Petri dish on a piece of moistened blotting paper for fifteen minutes, then dry carefully over a flame and stain with Leishman's or Giemsa's stain. A positive Widal will be shown by more or less marked clumping of the organisms overlying the suspected films with evenly spread organisms over the control halves. The stained slide may be used to make a differential leucocyte count. The method is very simple and rapid and if the result be positive a quantitative Widal test can then be made for greater accuracy. It is equally applicable to the detection of the paratyphoids.

Localized Tetanus.—Bazy (*Bulletin de l'Académie de médecine,* May 16, 1916) reports a case of shell wound of the left leg in which amputation at the upper third of the leg was performed on the next day and an injection of antitetanic serum administered six days after the injury. Meanwhile one subcutaneous injection of one mgm of strychnine had been given on five successive days owing to the patient's enfeebled state. The wound suppurated and failed to heal. A markedly hypersensitive whitish spot, apparently over the posterior tibial nerve, was noted, and dressing the wound gave rise to much pain and spasmodic contractions of the stump. In spite of free local spraying with one in 200 novocaine solution and a fresh injection of tetanus antitoxin these spasms increased until practically continuous. Sweats took place and the patient felt oppressed and lost the power to whistle, but neither trismus, dysphagia, nor sardonic grin appeared. Tonic convulsions extended from the injured limb to the opposite leg and to the arms and trunk, so painful as to cause the patient to cry out.

In accord with Babinski, Bazy made a diagnosis of tetanus and began the administration of large doses of chloral hydrate and smaller amounts of acetylsalicylic acid, with resulting almost immediate and permanent arrest of the convulsions. Careful bacteriological studies and guineapig inoculations failed to reveal the tetanus organism in this case. Although such failure is not regarded as definitely proving the absence of tetanus, Bazy is led to warn against concluding, in cases of more or less widespread muscular spasm attending a particularly painful suppurating wound, that the condition present is tetanus.

Summer Diarrhea.—E. Marx (*Berlin. klin. Woch.*, Dec. 13, 1915) states that the epidemic occurrence of summer diarrhea, its appearance in restricted localities, its disappearance when infected groups of persons are removed to other districts, and the absence from the stools of dysentery bacilli all suggest some other unrecognized cause. The author suggests that dietetic disturbances may so alter the nutrient factors in the gut that normally innocuous organisms may give rise to pathogenic varieties and that these may cause summer diarrhea. It is well known that changes in the nutrition may lead to the development of atypical variants of common organisms which differ from type by alterations in their fermentation and other chemical reactions. Further study along the suggested lines is much needed and should prove fruitful.

Frequency of Unsuspected Syphilis.—James S. McLester (*Journal A. M. A.*, June 24, 1916) says that by means of the Wassermann reaction syphilis was discovered in nearly nineteen per cent. of 300 cases seen in routine private practice. The cases were chiefly those which had been referred to the author on account of obscurity in diagnosis and so represented the less definite medical conditions. In sixty-one per cent. of the positive syphilitic cases no history, definite or suggestive, of syphilis could be obtained. The most striking feature of the findings, however, was that about half of all of the syphilitic cases came under the classification of neurasthenia in the common acceptation of the term. From these findings there seems to be indicated a more or less close connection with the symptoms of neurasthenia and syphilitic infection,—possibly the existence of a mild form of cerebrospinal syphilis as the cause of the neurasthenic symptoms.

Garibaldi's Wound and Pirogoff.—When the famous Italian patriot and soldier Garibaldi was shot in the right leg and captured in the battle of Aspramonte, the entire civilized world was interested in the fate of the popular hero. The gunshot wound, which refused to heal, was treated by a number of the best known surgeons of the day, Italian, French and English. At that time the great Russian surgeon, N. I. Pirogoff, resided in Heidelberg and was prevailed upon by the Russian students in that famed university town to offer his services to Garibaldi. This he did, refusing a fee of 1,000 francs offered by the students. In a letter written by Pirogoff after his visit to Garibaldi, quoted by S. Ia. Schtraich (*Roussky Vratch*, March 5, 1916), the Russian surgeon describes minutely the general's wound, throwing considerable light on the surgical methods employed in those days. It seems that the wound in the ankle joint was probed several times in attempting to discover the bullet, but the attempts failed. The wound was suppurating when Pirogoff saw it. It is interesting that as early as 1862 this great surgeon strongly advised against further probing or otherwise meddling with the wound, arguing that so long as the bullet was impacted and the joint still free from infection any attempt to dislodge and remove it might produce severe traumatism and result in irreparable injury. So long as a foreign body caused little disturbance by its presence it should be let alone until the time when its removal was distinctly indicated. He advised fresh air, removal to a dry climate, and watchful waiting. This was at a time when such famous surgeons as Nelaton, who was in attendance on Garibaldi, insisted that the bullet should be extracted at all hazards.

Typhus Fever in Serbia.—R. O. Moon (*Lancet*, May 27, 1916) states that the disease broke out when Serbia had been at war with Austria for five months and that the epidemic appeared to have originated among the Austrian prisoners, with its starting point in Valjevo near the Bosnian frontier. The infection was carried home by soldiers and by peasants wandering about and traveling clad in filthy clothes on crowded trains. The main circumstances favoring an outbreak of typhus were overcrowding, physical exhaustion and ill nourishment. When war was declared Serbia had only 400 physicians, and by July, 1915, so many had died that only 230 remained. Twelve British hospital units with 420 nurses and doctors by that month had the epidemic well under control. Scarcity of clothing to replace verminous garments while they were being disinfected was a great handicap, as was the lack of both warmth and food. Lack of fuel caused crowding and huddling for warmth and so spread disease.

An Improved Flexible Esophageal Bougie.—Dr. Robert C. Kemp, at a recent meeting of the Medical Association of the Greater City of New York, recalled that he had frequently directed attention to the fact that instrumental examination of the esophagus with the bougie was by no means always a safe procedure, and that the safest method was by the use of soft rubber stomach tubes of various calibres. This was particularly true for the novice. There were numerous esophageal bougies, and his own instrument most nearly resembled that of Lerche. The bougie had a small stem, about the diameter of a No. 11 French, made of round flexible wire, hollow, and covered with rubber, to which olives of various sizes could be threaded on a silk guide, if such were required. Slight or beginning stricture could be more readily determined by flexible bougies of various calibres. The flexibility apparently increased the delicacy of the touch, and rendered more ready appreciation of any irregularity or narrowing of the canal, even though slight, and small ulceration points could be more readily detected. Local anesthesia was rarely necessary for the introduction of the flexible instrument, which could be inserted with the patient's

head in the natural position (i. e., without extension) and with little disturbance. There were three stylets of different calibre, made of piano wire, furnished with each instrument. After the sound had entered the esophagus and passed to the point of stricture, if it was desired to stiffen the instrument in order to pass the stricture or to calibrate it, a stylet could be inserted with the head still in the natural position. Three degrees of stiffening could be secured. Complete protection to the stylet wires was afforded by bulbous tips, so that they could not possibly penetrate the wire tubing forming the shaft of the instrument. The rubber tube covering the shaft had upon it markings at one inch intervals, starting from the point of attachment of the olive so that the distance of the stricture from the teeth could be estimated. The ingestion of sweet oil previous to the passage of the bougie was an excellent procedure. It was always wise to make a digital examination of the lower pharynx, to determine whether adenoid tissue, vertebral deformity, a new growth, or other obstruction was present to interfere with the passage of the instrument. This bougie was believed to be safe for the examination of children.

Lead in the Urine in Trench Nephritis.—Charles Powell White (*Lancet,* May 13, 1916) reports that the urines from four cases of typical trench nephritis were examined for the metals which cause renal irritation and in all of the specimens notable traces of lead were found. That this occurrence was not an accident was shown by the fact that repeated examinations of the urines, taken at different times during the course of the illness, always revealed traces of the metal. Investigation showed that the lead might have been derived from the use of canned foods which had taken up some of the lead from the solder used in closing the tins. Boiling a solution of sodium chloride for ten minutes in a can containing a small piece of solder caused the solution of an appreciable amount of lead, thus confirming the possible contamination of tinned foods with that metal.

Early Diagnosis of Intussusception in Children under Three Years of Age.—Dr. A. W. Abbott, of Minneapolis, at a recent meeting of the Western Medical Association, said as children under three years of age had too little intelligence to describe their symptoms, a knowledge of their clinical behavior was most important. Twelve children, three years of age or under, were observed, and the following conclusions reached: 1. A sudden violent abdominal pain, accompanied by a regurgitation of its stomach contents, in a child otherwise well, initiated the attack in 100 per cent. of the cases. 2. Recurring pains, varying in intensity, but regular in periodicity, accompanied by the assumption of peculiar positions, generally the prone, in those strong enough to move about, occurred in 100 per cent. of those noted. In cases beginning in collapse, twenty-five per cent., these periodical pains were often indicated only by regularly repeated moans and drawing up of the limbs. 3. An abdominal tumor could be made out somewhere in the course of the colon in ninety-two per cent. 4. The stools did not contain feces in ninety-one per cent. 5. Mucous stools are recorded in eighty-three per cent. 6. The foregoing indications should strongly suggest intussusception within forty-eight hours of the attack. 7. Blood in the stools added to this certainty of diagnosis, but it might be absent in seventy-seven per cent. until after the second day. 8. Instead of distention, they might expect a flaccid, scaphoid abdomen. 9. Recurring vomiting was not usually one of the earliest symptoms, being absent in eighty-one per cent. until the second day, or later in their cases, and in exceptional cases there was no vomiting. 10. Positive identification of the intussusception by the finger in the rectum was pathognomonic, but might be demonstrable in only fifty-five per cent. 11. The virulence of the disease and its mortality depended not so much upon the time elapsed before operation as upon the intensity of the strangulation of the mesenteric circulation. These observations were supported by the following mortality account: Of the twelve cases, eight ended in recovery, four being fatal. Of the non-collapsing cases, eight ended well, and one was fatal. Of those beginning in collapse, one terminated in recovery, and three were fatal. To protect all cases, the earliest possible diagnosis and operation were imperative.

Causes and Prevention of Trench Foot.—Basil Hughes (*British Medical Journal,* May 25, 1916) divides trench foot into three stages, of which the first is edema of the plantar surface of the foot spreading to the dorsum, accompanied by tenderness on deep plantar pressure: the second stage is that of numbness with swelling and sluggish circulation, while the third stage is that of gangrene. The causes are fatigue and exhaustion as predisposing factors, with mechanical nervous stagnation from sitting on the firing steps of trenches with the feet hanging down, thus producing exudation of serum into the feet.

Pleurisy and Bronchoalveolitis — Secondary to Tuberculosis of the Tonsil of the Same Side.—The case reported (*Riforma medica,* May 22, 1916) was in a boy of fourteen years who was attacked in 1910 by acute tonsillitis which, after a week of apparent cure, recurred with mild fever of long duration and general weakness. This tonsillar condition was followed by an apical pleurisy with bronchoalveolitis which resolved completely in two months. One year later a second attack of catarrhal angina occurred, lasting fifty-two days. The case came up for tonsillectomy and, after removal, the left tonsil showed tuberculosis. Undoubtedly there was a relationship between the tuberculous process of the tonsil and that of the apex, otherwise it is impossible to explain the coincidence twice in one year of pleuropulmonary manifestations on the left side corresponding to the tonsillar focus of tuberculosis. The question of possibility of the tonsillar tuberculosis being secondary to that in the lung is excluded by the fact that ordinarily such secondary infection occurs from sputum, which at no time was present in this case, even cough being absent.

Proceedings of National and Local Societies

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, May 16, 17, and 18, 1916.

The President, Dr. W. STANTON GLEASON, of Newburgh, in the Chair.

Medical Examination of School Children.—Dr. F. PARKE LEWIS, of Buffalo, spoke on the vision of the school child and stated that the extraordinary conditions which had arisen during the past year in connection with the world war had compelled them to look upon some of their social problems from a new angle. They had been forced to believe that principles upon which the republic was founded, far from being absolutely established, were still on trial, that democracy was still an experiment, and that its success was wholly dependent upon the character of those who constituted the electorate. They had been made to believe that the stream of immigrants that had poured into this country during the past decades had brought with it vast numbers who had been barely able to support themselves and their numerous progeny, and many of these were of low grade physically, and that others had in their bodies the seeds of disease or of infirmities which they transmitted to their offspring. The necessity which was now being so forcibly emphasized of internal preparedness required that the child of today should have remedied every defect which limited its potentialities. It became then a matter of self preservation on the part of the State to protect its own future by using every possible effort to make each child as capable of higher responsibilities of citizenship as its conditions and circumstances would permit. This was happily being met in some measure by the medical examinations in the schools. In this brief consideration of the subject, it was intended to emphasize the following propositions: First, that in order that they might know how much importance to attach to the defects of the eyes, they must have exact data as to their incidence, their character, their corrigibility and their influence in retarding the normal progress of a large number of scholars. Second, in order that they might acquire these facts, standardized methods must be devised applicable to the entire school population. Third, measures must be considered for the analysis of the material so gathered, that practical and facile methods might be employed in each case. In order that they might realize how inadequate were their present methods, it was necessary only to refer to any of the reports of the eye examinations of large numbers of children.

Careful work had been done in Pennsylvania; in the report of 1914-15, in the fourth class districts, the number of pupils inspected amounted to 469,199; among these with visual defects were found 83,748, or 17.8 per cent. Pupils having other eye defects numbered 5,512. It became necessary very clearly to discriminate between the various conditions that were classified in bulk as defects of the eyes. Until such discriminations were made, the records would show that vast numbers reported as having defective sight remain uncorrected and were reported as unfinished cases. In many cases this was inevitable.

What disposition should be made of such pupils in the classification and arrangement of the school? They could not see adequately to maintain their position in the classes with those whose eyes were good; therefore, some other method must be devised by which they might be relegated to special classes or other provision made for their instruction. The teacher, with not more than fifty children in her class, had opportunities for observation superior to those of any outside investigator who came temporarily into the examining room. The methods employed in the correction of eye defects were not always the best; when the work was done for a poor child, the patient was usually referred either to a public dispensary or to an optician. The refractive work provided in public dispensaries was too frequently done in a hurried and careless way. If the poor child was sent to an optician, the work was even more slightingly done. The small amount paid for the lenses by those who were poor was often a burden. Since the State concerned itself with the welfare of the child to such a degree as to insist upon the child being examined and geting spectacles, it should go still further to see that the examinations were made under right conditions and that suitable and well fit ting glasses were provided at a minimum cost. When the parents were too poor to pay, glasses should be supplied by the school authorities gratuitously, just as books were provided for study. This could not be done when the school child was sent where examinations were made perfunctorily.

Through the efforts which had been made by the State medical inspector of schools, Dr. William A. Howe, a large number of careful ophthalmologists had offered their services for the gratuitous examination, at specified times and places, of such necessitous cases as might be referred to them. This was an excellent beginning. But the problem was too big to be met in this way. The importance of the municipality establishing its own clinic for refraction, and supplying the poor pupils with glasses, was emphasized in a paper read at the Fourth International Congress on School Hygiene by Dr. Louis C. Wessels, in which he pointed out that from an economic standpoint it was a saving to see that the children in the public schools had such eye equipment as would enable them adequately to do the work that was required of them. Such a clinic had been established in Philadelphia. There were very few children who knew how the eyes should be used, and it was suggested by a committee chosen by the National Educational Association, and later by a committee of women school principals in New York, that the child, when he began to use books, be taught how they should

be used, and the following simple recommendations be printed on the first blank page of every school book:

1. Take care of your sight; upon it depends much of your safety and success in life. 2. Always hold your head up when you read. 3. Hold your book fourteen inches from your face. 4. Be sure that the light is clear and good. 5. Never read in the twilight, in a moving car, or in a reclining position. 6. Never read with the sun shining directly on the book. 7. Never face the light in reading. 8. Let the light come from behind you or over the left shoulder. 9. Avoid books or papers printed indistinctly or in small type. 10. Rest your eyes frequently by looking away from the book. 11. Cleanse the eyes morning and night with pure water. 12. Never rub the eyes with your hands or an unclean towel, handkerchief or cloth.

Another reason why permanent records should be made of all school children's eyes was found in the Workman's Compensation Act, which had recently been put upon the statutes of the State. It was constantly becoming more evident that with the assumption of responsibility on the part of the employer for injuries received by the employee in the performance of his duties, that there must be an assurance of the existence of a normal physical condition on the part of the workman who was thus protected, but if there was an abnormal condition present this must be recognized and known in order that the extent of the injury might be ascertained. It must be evident that if the examination of the eyes of all school children of the State were so standardized as to make it a part of the routine work, if these records were permanent and available, they would serve, not only as a basis for the immediate relief of difficulties limiting the child's possibilities of usefulness, but would constitute an essential feature in their preparedness program in giving them the important and necessary data.

Practical Experiences in Medical Inspections in Rural Sections.—Dr. William A. Howe, of Albany, stated that during the first year of the administration of the medical inspection law, many impressive and varied experiences had arisen throughout the State. Many grateful parents had written the department thanking it for the wonderful relief extended to their children. Thousands of children had been placed on a higher plane of physical fitness, thus enabling them to make more normal progress in school. While most of these cases, as might be expected, belonged to those commonly seen, many had been more impressive. Two children had come under his observation with congenital cataract whose vision amounted to practically nothing. They had been successfully operated on, restored to vision and placed in school, where satisfactory progress was now being made. In one family three were found with so little vision as to render regular school work impossible. The two of school age had recently been placed in the New York State School for the Blind at Batavia, where they would receive an academic education, taught some vocation, and be made self sustaining citizens. Another child with a badly disabled foot from infantile paralysis had been successfully treated by tendon transplantation. In two instances where pupils were incorrigible, impertinent, backward, and unmanageable in school, they improved promptly after the removal of septic tonsils and obstructing adenoids. Several cases of tuberculosis had been found among teachers, while in one district this disease had existed among the pupils for nearly fourteen years. Many pupils throughout the State, either in the pretuberculous or incipient stage of the disease, had been recognized and greatly benefited by sanitary or institutional treatment. The fact that tuberculosis increased so rapidly among children during their first years of life in school should demand the serious consideration of not only health workers but educators as well. Their joint energies should be directed to determine the factors entering into these alarming conditions, so that the proper preventive measures might be speedily administered. Increasing interest was being manifested in medical inspection in the rural sections of the State. This was indicated not only in a general demand for more efficient services at the hands of the inspector, but in systematic efforts to extend relief to children needing attention. A few days ago one of the village districts reported fifty cases of obstructed breathing among children of foreign parentage or from dependent families. During the next few weeks these would be referred to specialists in Rochester who had generously designated free services to deserving children. In another village in western New York, certain school rooms were being utilized as a temporary hospital, where, under the supervision of an experienced nurse, physicians and surgeons were administering relief to local children. Again, in Schenectady, seven rural schools had united in the employment of a school nurse, who was devoting her entire time to inspecting the children and to the improvement of school and home conditions. This nurse, though employed only for the past three months, had already accomplished such splendid results as fully to demonstrate the practical value of such services. In another section of the State he found a rural teacher referring many of her children to specialists in Buffalo, where embarrassing physical defects had been relieved, thus insuring to pupils far greater progress in school.

Only physicians interested or willing to take an interest in the work should become medical inspectors; the utmost care should be exercised in all examinations, and definite care should be shown in giving information to parents as to the defects found; physicians should receive a fee commensurate with the services rendered, which on all occasions should be his best; physician, teacher, parent, pupil, and nurse should cooperate in the entire system of school inspection; the real success of school inspection should be measured by the thoroughness with which the examinations were made and the results accomplished.

The Neuropathic Child.—Dr. Edward B. Angell, of Rochester, thought the best description of the neuropathic child was that given by Dr. Francis Warner, of London, who had examined 100,000 school children. He described the characteristic

manifestations of the neuropathic condition as headache, difficulty in getting to sleep, grinding of the teeth, delicate physical condition without actual disease, lack of appetite, and tendency to be easily fatigued. These children were generally well made in body and had good heads, they had well cut features and fine skins and usually light complexions. There was a weakness and an overspontaneity. There were uncontrolled movements without coordination. Later impressionability and imitativeness showed that the child's mind was impressed by what it saw. With growth development there was power to arrest the motor concept and to modify or even deny its inhibition. Thus they acquired a control over the senses, by which the mind gradually acquired desire and volition, the relative value of sensory impressions and motor action. Another quality developed was retentiveness and coordinating action which was the result of many past impressions, desires, and resulting movements. The normally constructed brain of the healthy child in its motor action presented well balanced muscular movements. The relationship between the muscle activity and the brain activity was very direct. Basing his test on these facts Doctor Warner had found that requiring the child to raise his arms and hold them out straight in front in a horizontal position was a test of the nervous condition and the degree of fatigue. If the latter was present the child did not hold both arms parallel, or dropped one arm, or one hand, or in the very neurotic the knuckles were pointed directly backward.

Self control could not be too thoroughly established for the growing child, since without it there was an unstable equilibrium which later gave rise to the vagaries of neurasthenia and hysteria. If they studied the nervous child they would find that his position might be one of erectness, of assurance, or defiance, or it might be drooping and self conscious, or one of weariness, or fatigue, the latter being common in girls.

Another habit easily acquired by the nervous child was that of introspection, and this led later to unstable equilibrium and self consciousness to the detriment of efficient mental activity. Doctor Angell had observed seventy-five or eighty cases of typical nervous children and had found that alcoholism and insanity had entered in as factors in about one third of the cases, while the arthritic diathesis was present in about thirty per cent. In only one case did he find tuberculosis in the family, but tuberculosis probably played a more important part than this indicated in the transmission of an unstable nervous constitution. In about twenty-five per cent. of these cases the condition could be traced to abnormalities in pregnancy or delivery. Faulty metabolism, such as constipation, headache, mental depression, irritability, and a poor circulation were characteristic evidences of disturbed nutrition. There was defective nutrition in about two thirds of the cases, and nearly one third were the victims of night terrors. He believed that protein entered too much into the diet. Fresh air was a most important factor in the treatment of this type of child. The Boy Scout movement was an excellent thing in developing the correlation of muscular and physical activities, teaching the boy self control and how to adjust himself to life.

The Effect of Malformation and Infection of the Oral Cavity of the Child upon Its Future Health.—Stephen Palmore, D. D. S., of Poughkeepsie, by invitation, said that the fact that a man belonging to the dental profession had been asked to address this society was significant of the change that had come to pass; he quoted from the writings of Dr. Victor C. Vaughan to show the relations between mouth infections and various constitutional conditions. These made it evident that nothing was more important than hygiene of the mouth of boys and girls, for upon it depended the health of the men and women of tomorrow. Evidence in support of this statement might be brought forward from many authorities. Medicine today recognized the importance of prophylaxis, and in dentistry it found the prophylaxis of many conditions that had been puzzling to the physician. Malformations were of the utmost importance and were so common that they rarely saw normal mouths and teeth. This he attributed to the mixing of the races and the fact that enough time had not elapsed to evolve a definite type. To the proper moulding of the human face a full complement of teeth was requisite. Where there was malformation there was malocclusion, and this was the rule rather than the exception. The anatomy of the mouth and teeth was such that the loss of one tooth ultimately disturbed the balance of the whole. Therefore, one cause of dental deformity was the loss of one tooth. Thumb, lip, and tongue sucking was another cause of deformity, causing malocclusion and a narrowing of the palatal arch and basal construction. It was, therefore, important for the rhinologist to work with the dental surgeon when it came to the treatment of mouth deformities involving the palatal arch, for such deformities retarded the function of the tongue, lips, and nasal passages.

Mayo and Hunter had emphasized the importance of oral sepsis as a source of infection. In the demonstration of alveolar abscesses the x ray had been a great help to the dentist as it had to the physician. The value of oral prophylaxis had been amply proved by the establishment of dental dispensaries; in every city and town there should be a dental clinic. Pyorrhœa alveolaris was not a disease of childhood, and with proper prophylaxis and the correction of malocclusions it could be prevented. They might put it down as an axiom that a clean tooth never decayed, that teeth in good occlusion were easy to keep clean, and therefore teeth in good occlusion never decayed. The value of oral prophylaxis had been amply demonstrated in the German army. Attention had been given to this matter among the school children of Germany and as a consequence few of the German soldiers required dental care, while, on the other hand, such prophylactic work had not been carried on to the same extent in England, and there was a great deal of dental work to be done among the soldiers of the English army.

In September, there would be a legalization of dental hygienists, which would make it possible to have a trained corps of dental assistants to bring

the importance of dental hygiene before the public. By the concerted action of physicians and dentists, the coming generation would be healthier than the present one.

Dr. John L. Heffron, of Syracuse, said it might be of interest to know how they were taking care of refraction work in their town. The work was done by a volunteer staff of dispensary doctors. This year the department of education of the city had undertaken to employ doctors from the dispensary at the nominal salary of part time medical inspectors to care for the eyes of the school children. These men had had good training in the dispensary and as a consequence the school board got good service.

Dr. Moss Keschner, of New York, was glad that Doctor Angell had called attention to the neuropathic child. As a rule, the general practitioner gave this type of child scant attention. Then the mother brought such a child to him, complaining of night terrors, bed wetting, and nervous symptoms, he usually prescribed bromides and Fowler's solution and let it go at that. In this class of children they often had a greater problem to solve than in actual organic disease. The many details of environment and economics must be taken into consideration. These were the children that later filled the asylums, homes for epileptics, and reformatories, and their treatment should be regarded as an important and serious problem.

Dr. B. W. Whitbeck, of New York, with reference to the examination of children, would like to bring out the influence of flat foot upon the general condition of the child. The records of the New York schools showed that about sixty per cent. of the children presented a condition of weak or flat feet, and it was his opinion that seventy-five per cent. would be more nearly correct. He had inquired at Washington as to the disabling effects of flat foot in the United States army and navy, and had found that they were throwing out many candidates on account of this defect. Children with this defect were often backward in school, tired, would not play or eat. He had had such a case in which a boy had been treated with tonics, sent to an oculist who prescribed glasses for the relief of headache but all without avail. The boy finally went to his family physician who found that he had a hollow back and flat feet. This boy was treated with proper orthopedic appliances, and in a short time his general condition improved and he took off his glasses. He believed that flat foot was one of the conditions incident to civilization, and probably standing with the toes out had something to do with it. Some children never had good feet; they were flat footed from babyhood, but the condition was frequently not noticed until the child grew older and suffered pain. It was not merely a question of whether the foot was flat, but of whether it was functioning. It was not so much a question whether the feet were flat, as whether they were weak. Many persons had flat feet and yet went through life without symptoms; it all depended upon whether the foot functioned or not.

Dr. Frank Overton, of Patchogue, had been interested in the references to instances in which private physicians failed to detect the defects of school children. In his town there was efficient cooperation between the private physicians and the school inspectors. This was true in many towns, but he understood that there were places where there was not this cooperation. It was one of the functions of this medical society to bring about such cooperation and he believed it was doing this more and more.

Dr. Edward B. Angell, of Rochester, wished to go on record as being in accord with what Doctor Keschner had said. They should call the attention of the general practitioner to such cases. There were many conditions that he had not referred to in his paper. He had not referred to dementia præcox. It was sometimes difficult to tell whether they were dealing with a neurasthenia or a dementia præcox. He had had a case of dyspituitarism in a boy who presented feminine characteristics and an utter lack of any sense of responsibility. In this case treatment with pituitary extract had brought about great improvement both physically and mentally. Such cases showed that something could be done by a careful study of these cases in youth. The points brought out as to the relation between flat foot and hollow back and their effect on the general health were very important. Doctor Warner, of London, to whom reference was made in the speaker's paper, had stated that he had found many cases of hollow back and had observed that it bore some relation to flat foot, but he had not attempted to explain it.

Letters to the Editors.

ADRENALINE PER OS?

St. Louis, Mo., *June 24, 1916.*

To the Editors:

Having suffered with an abscess of the transverse colon, three weeks ago, it was suggested to me after twenty-four hours of excruciating abdominal pain, by Dr. George Richter, of St. Louis, that I try fifteen drops of adrenaline in one tablespoonful of water as often as required, for the relief of this pain.

Fearing to take morphine because of its muscular fixation powers and its aftereffects, I gladly welcomed the suggestion, as adrenaline had been used in Vienna in the surgical wards with splendid results, the patients themselves asking for the "good drops," on the approach of abdominal pain.

At the suggestion of Dr. C. A. L. Reed, of Cincinnati, I told Doctor Andrews, chairman of the surgical section; he requested me to take two minutes of the afternoon session, which was held conjointly with the internal medical section, Wednesday afternoon, at the Detroit meeting of the A. M. A.

I have suggested it in a gallstone case and used it in kidney colic, in both of which cases it gave splendid relief.

I consider it a panacea in all cases of abdominal pain.

In fifteen drop doses in a tablespoonful of water it can be given as often as required internally, its action being different when administered hypodermically.

I believe adrenaline could be used as a substitute for twilight sleep. Leland Boogher, M. D.

[This letter is doubly interesting, first, on account of the announcement of the discovery of analgesic properties in adrenaline, and, second, because the product has always been considered inert when administered *per os*. Even the manufacturers insist that suprarenal preparations must be given hypodermically in order to produce either a physiological or a therapeutic effect.—Eds.]

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

Formulaire des Médications Nouvelles et des Traitements Nouveaux Pour 1916. Par Le Dr. H. Gillet, ancien interne des Hôpitaux de Paris, Chef de Service à la Policlinique de Paris. Dixième Edition Entièrement Refondue. Paris: Librairie J. B. Baillère et Fils, 1916. Pp. xx-324.

The author has presented in a very convenient form which can be readily slipped into the pocket a clear and concise statement of all that needs to be known by the practitioner of medicine of the newer forms of medication. The matter is arranged alphabetically under the therapeutic indications, which makes for convenience in reference. The information is tabulated and presented in the most terse manner consistent with clarity. As a result of the condensation a really surprising amount of information is crowded into this small handbook. The newer vaccines, serums, and opotherapeutic preparations, as well as the newer uses of the standard drugs and chemicals are given, making the revised edition a valuable book of reference.

Pellagra. Part I. A New Contribution to the Etiology and Pathogenesis of Pellagra. By Professors GIULIO ALESSANDRINI and ALBERTO SCALA, of the Institute of Experimental Hygiene of the University of Rome. Illustrated with the Original Plates, and Drawings made by the Translator. Translated from the Italian by E. M. PERDUE, A. M., M. D., D. P. H. *Part II. Pellagra in the United States.* By E. M. PERDUE, A. M., M. D., D. P. H., Professor of Preventive and Tropical Medicine, Eclectic Medical University, Director Johnson's Pathological Laboratory for Cancer Research, Kansas City, Mo.; President, American Association of Progressive Medicine. Kansas City, Mo.: Burton Publishing Co., 1916. Pp. 362. (Price, $3.)

The opening remarks in the preface are sufficient proof of the antagonistic attitude of the mind of the translator to proved facts and methods of investigation. That which he approves of is correct, all else is incorrect.

Interesting as are the contributions of Alessandrini and Scala concerning the cause of pellagra, their contentions are not supported by clinical results. According to them, "pellagra is the effect of a chronic intoxication which is caused by silica in colloidal solution in water of determinate composition, and therefore may be defined as a disease caused by colloidal minerals."

The recent report by Jobling and Petersen of the epidemiology of pellagra in Nashville, Tennessee, is a much more rational presentation and explanation than the foregoing.

Interclinical Notes

Here is some interesting history from *Commerce and Finance* for June 7, 1916, written apropos of the death of Clements R. Markham: "Clements R. Markham, who died recently, must be considered the conqueror of India. Markham had been a traveler and explorer and visited Peru in 1859, where he saw that the cinchona trees, from whose bark quinine is extracted, were being destroyed so rapidly that the world's supply of this valuable remedy for malarial fevers would soon be gone. He induced the English government to plant the tree in India, and its culture there lowered the cost of quinine so greatly that it became a popular remedy. Only the rich had been able to afford it previous to Markham's cinchona culture in India. In 1914 the United States imported nearly 4,000,000 pounds of cinchona bark and nearly 3,000,000 ounces of quinine alkaloids, showing the wide use of quinine in this country. Markham died at the age of eighty-six years from burns caused by upsetting a candle he had used while reading in bed. Strange it is that such a progressive man should have met his end from the use of that now decorative illuminant—the candle!"

An unusual story, by a beginner, we believe, is A Little Folding of the Hands, in the July *Century*. Hannah Abert is the authoress. It shows great promise and has one or two really professional touches. One is the omission of the name of the doctor who opens the story with a gloomy prognosis concerning the illness of the elderly but delightful heroine.

* * *

Contemplation of the full page picture in the *Outlook* for June 21st of the impressive looking building of the Massachusetts Institute of Technology, makes us think that concrete would be a good material out of which to build hospitals. This building is free from tremors, is absolutely fireproof and otherwise indestructible, while the possibilities of concrete in other directions are limited only by the talents of the architect.

* * *

The *Medical Press and Circular* for May 17th remarks that Sydney Smith never said that an operation was necessary to get a joke into a Scotchman's skull. The true story, it says, is told by Lady Holland, in her biography, which is thus quoted by Walter Jerrold: "William Chambers, in conversation with Sydney Smith, very justly alleged for the Scotch that they had, after all, a considerable fund of humor. 'Oh, by all means,' agreed the witty clergyman, 'you are an immensely funny people, but you need a little operating upon to let the fun out. I know of no instrument so effectual for the purpose as a corkscrew.' Sydney Smith described real wit 'in midwife's phrase, as a quick conception and easy delivery.'"

* * *

We believe that it was Max Nordau who, in 1896 or thereabouts, introduced the unconscious or subconscious mind to the public. After a long period of quiet, the theory seems to be enjoying a renascence. We are reading everywhere of the astonishing effects of the subconscious mind on digestion and other functions. We used to think that dyspepsia caused the most terrible gloom, but it appears that we had the cart before the horse—it is the gloom that gives rise to the dyspepsia. Instead of bismuth and the alkalies, or a course of the mineral acids, we must now give the patient cheering suggestions, with a preliminary hypnotic nap if necessary. The number of quacks, male and female, working along these lines in New York city alone, is astonishing—and we omit the followers of the big cults.

* * *

Peccavimus, cries *Collier's* for June 3, 1916, and continues: Henry La Fontaine, for twenty-two years a member of the Belgian Senate, has for more than a year past been a visitor in America. In an article written for the New York *World*, Senator La Fontaine discusses our American civilization with a great deal of sympathy, but he expresses disappointment in our newspapers and magazines—as witness the following sentence: "Daily into many millions of human brains the American press imprints *facts* which are generally of so little importance that in thirty days they are forgotten, and it never tries to sow *ideas* which would bear lasting fruit." This is a brief statement of a fault which has pervaded American journalism. Are we doing anything to correct it?

Medical journals, we think, try to sow ideas, and there are in this country several periodicals with which the doctor would be sorry to part for that very reason.

* * *

The *Survey* for May 20th gave a couple of pages to the discussion of the new dispensaries to be conducted with the idea of exacting a fee from those able to pay. We understand that men with an income of $1,200 will be expected to pay. Those who criticize the plan because the physician is not taken into consideration have, we believe, the wrong viewpoint. The medical profession seeks constantly to eliminate itself. As soon as it has discovered the origin of all diseases and instructed the laity in prophylaxis and hygiene, it will finally lay down the prescription and the lancet. Meanwhile it must take into account problems not its own, and one of these is the pauperization of the moderately well to do. Many visitors to outdoor clinics are willing to pay and it is well that they should pay, at the same time securing the best available advice. Later on, treatment will be free to all, and the emoluments are to come from the State. It is thus that we interpret the symptoms; our approval is neither here nor there.

Official News

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States for the week ending June 24, 1916:

Abeken, F. G., Surgeon. Ordered to Naval Hospital, Great Lakes, Ill.

Bloedorn, W. A., Passed Assistant Surgeon. Detached from the Navy Yard, Washington, D. C.

Biello, J. A., Passed Assistant Surgeon. Detached from the *Kentucky* and ordered home to await orders.

Conner, W. H., Passed Assistant Surgeon. Detached from the *Fulton* and ordered to the *Kansas*.

Dessez, P. T., Passed Assistant Surgeon. Ordered to the Navy Yard, Washington, D. C.

Grieve, C. C., Surgeon. Detached from the Naval Hospital, Great Lakes, June 26, and ordered to the *Utah*.

Hayward, A. B., Passed Assistant Surgeon. Ordered to the *New Orleans*.

Thomas, C. G., Passed Assistant Surgeon. Detached from the Naval Station, Guam, and ordered to the *Fulton*.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers in the United States Public Health Service for the seven days ending June 28, 1916:

Boggess, John S., Surgeon. Directed to proceed to Seattle, Wash., to take temporary charge of the Service during the absence of Surgeon Lloyd; leave of absence for twenty-five days from July 10, 1916, granted by bureau letter of June 10, 1916, revoked.

Cox, O. H., Assistant Surgeon. Ordered to report to the commanding officer of the Coast Guard cutter *Apache*, Baltimore, Md., for physical examinations of Coast Guard men; leave of absence for fourteen days from July 1, 1916, granted by bureau letter dated June 3, 1916, revoked.

Foster, M. H., Surgeon. Leave of absence for one month from July 5, 1916, granted by bureau letter dated May 23, 1916, revoked.

Gwyn, M. K., Surgeon. Detailed as a member of board convened at the marine hospital, Stapleton, N. Y., June 26, 1916, for the examination of applicants for cadetship, U. S. Coast Guard, vice Passed Assistant Surgeon C. P. Knight, relieved.

Lloyd, B. J., Surgeon. Directed to proceed to El Paso, Texas, for special temporary duty along the border in the work of preventing the introduction of typhus fever from Mexico.

Marshall, E. R., Passed Assistant Surgeon. Directed to proceed when necessary to Warren and Newport, R. I., and other places in the Customs District of Providence, to make quarantine inspections of arriving vessels.

Myers, C. N., Organic Chemist. At the request of the commissioners of Internal Revenue, directed to proceed to New York to attend the trial of a suit in regard to the proper classification of novocaine.

Porter, J. Y., Quarantine Inspector. Directed to make inspections of the quarantine stations on the coast of Florida.

Robinson, D. E., Surgeon. Leave of absence for one month from July 1, 1916, granted by bureau letter dated June 5, 1916, revoked.

Roth, G. B., Technical Assistant. At the request of the commissioner of Internal Revenue, directed to proceed to New York, to attend the trial of a suit in regard to the proper classification of novocaine.

Stimson, A. M., Surgeon. Leave of absence for one month from July 1, 1916, granted by bureau letter dated June 10, 1916, revoked.

Sweet, E. A., Passed Assistant Surgeon. Detailed to deliver an address on public health, June 29, 1916, at a meeting of the American Institute of Homeopathy, Baltimore, Md.

Warren, B. S., Surgeon. Directed to proceed to New York, N. Y., about June 27, 1916, for investigation of health insurance.

Williams, L. L., Jr., Assistant Surgeon. Granted three days' leave of absence from June 21, 1916.

Boards Convened.

Board of medical officers convened at Detroit, Mich., for the reexamination of alien. Detail for the board: Senior Surgeon H. W. Austin, chairman; Surgeon H. W. Wickes, member; Acting Assistant Surgeon K. L. Weber, recorder.

Boards of commissioned medical officers convened July 10, 1916, for the examination of candidates for appointment as assistant surgeons, as follows: Marine Hospital, San Francisco: Detail for the board. Senior Surgeon L. L. Williams, chairman; Assistant Surgeon D. S. Baughman, recorder. Marine Hospital, Chicago, Ill.; Detail for the board, Surgeon J. O. Cobb, chairman; Assistant Surgeon R. R. Spencer, recorder.

Births, Marriages, and Deaths

Born.

Aronson.—In New York, on Saturday, June 17th, to Dr. and Mrs. Louis Aronson, a son.

Married.

Bull-Fulwider.—In Denver, Colo., on Saturday, June 17th, Dr. Heman R. Bull and Miss Ruth B. Fulwider.

Carpenter-Dechert.—In Schuylkill Haven, Pa., on Friday, June 23rd, Dr. J. Stratton Carpenter, of Pottsville, Pa., and Miss Claire Beck Dechert.

Hardinger-Calkins.—In Cincinnati, Ohio, on Saturday, June 17th, Dr. Ralph W. Hardinger and Miss Helen M. Calkins.

Ryder-McWeeny.—In Bellows Falls, Vt., on Tuesday, June 20th, Dr. Walter R. Ryder, of Boston, Mass., and Dr. Bernadette McWeeny.

Schurtz-Bliss.—In Streator, Ill., on Wednesday, June 14th, Dr. Carl Schurtz and Miss Alta Bliss.

Schade-McClain.—In Dubuque, Iowa, on Thursday, June 15th, Dr. William J. Schade, of Lancaster, Wis., and Dr. Grace McClain.

Williams-Mulvanity.—In Boston, Mass., on Monday, June 26th, Dr. David L. Williams and Dr. Sadie A. Mulvanity.

Williams-Elliott.—In Stanford, Cal., on Thursday, June 22d, Dr. J. Harold Williams and Miss Christabel Elliott.

Died.

Alpers.—In Rantoul, Ill., on Sunday, June 18th, Dr. J. H. Alpers, aged eighty years.

Ashby.—In Baltimore, Md., on Friday, June 26th, Dr. Thomas Ashby, aged sixty-eight years.

Bell.—In Atlanta, Ga., on Monday, June 19th, Dr. W. Jay Bell, aged forty-seven years.

Brown.—In Norridgewock, Me., on Friday, June 16th, Dr. Llewellyn F. Brown, aged eighty-one years.

Cook.—In Cincinnati, Ohio, on Saturday, June 17th, Dr. Henry J. Cook, aged fifty years.

Corbett.—In Washington, D. C., on Monday, June 5th, Dr. Elizabeth J. Corbett, aged eighty years.

Courtright.—In Newark, N. J., on Wednesday, June 28th, Dr Everett P. Courtright, aged forty-eight years.

Donnelly.—In Troy, N. Y., on Thursday, June 22d, Dr. James M. Donnelly, aged sixty-eight years.

Gardner.—In Atlanta, Ga., on Monday, June 19th, Dr. Grafton W. Gardner, aged eighty-nine years.

Glass.—In Booneville, Ky., on Wednesday, June 21st, Dr. A. M. Glass, aged fifty-three years.

Koontz.—In Independence, Va., on Tuesday, June 20th, Dr. Andrew J. Koontz, aged fifty-seven years.

McDermith.—In Denver, Colo., on Thursday, June 15th, Dr. Sampel T. McDermith, aged sixty-eight years.

Orr.—In Belmont, N. C., on Wednesday, June 21st, Dr. Nathaniel A. Orr, aged thirty-nine years.

Paquin.—In Kansas City, Mo., on Friday, June 23rd, Dr. Paul Paquin, aged fifty-six years.

Purinton.—In Kenduskeag, Me., on Tuesday, June 20th, Dr. Andrew M. Purinton, aged seventy-eight years.

Smith.—In New London, Conn., on Tuesday, June 20th, Dr. John O. Smith, of Canterbury, Conn., aged seventy-six years.

Young.—In Fredericksburg, Va., on Sunday, June 18th, Dr. Thomas S. Young, aged eighty-six years.

SYPHILIS OF THE NERVOUS SYSTEM.*

BY EUGENE D. BONDURANT, M. D.,
Mobile.

One in five of the inhabitants of the United States has the taint of syphilis in his blood. One in five of those who contract syphilis receives some material injury to the nervous system therefrom. One in five of the patients in our State insane hospitals is placed there by syphilis, this disease now ranking first as a cause of insanity. Most of the organic nervous disease met with in practice is a result of syphilis. The already enormous and steadily increasing amount of syphilitic disease, and the disastrous results of its all too frequent involvement of the nervous system, introduce one of the most serious of the medical, economic, and sociological problems which human civilization is now called upon to face.

Syphilis produces pathological changes in the organs of the nervous system in all respects similar to those caused in other parts of the human body; i. e., the productive inflammatory process which characterizes syphilis involves the meninges, the nerve sheaths, and the intrinsic connective tissues of the central nervous organs and peripheral nerves, causing thickening and proliferative overgrowth with sometimes granulomatous infiltration or tumor formation. The walls of the bloodvessels become diseased, leading to circulatory disturbances, occlusions, hemorrhages, and softenings. The damage to the nerve cells from syphilis is usually a secondary result of the inflammatory and other changes brought about in the connective tissues, bloodvessels, and meninges, although the directly toxic effect of the poison of syphilis upon the neurons contributes somewhat to the pathological process.

The clinical symptoms and disease syndromes caused by the action of the syphilitic poison upon the nervous system are merely perversions of, or qualitative, alterations in normal nerve cell function. The clinical picture of any syphilitic nervous disease is determined by the distribution and severity of the lesions, and by the functions of the cell masses which become involved.

Among these diseases and syndromes we note acute and chronic forms of peripheral neuritis, acute and chronic myelitis, specific poliomyelitic inflammation and degeneration in the gray matter of the cord and cranial nerve nuclei; optic nerve atrophy and other cranial nerve palsies; headaches, neuralgias, spasmodic neuroses, organic epilepsies, and acute psychoses; apoplexies, both thrombotic and hemorrhagic; granulation tumors of brain and cord; bony exostoses and fibrous thickenings causing pressure; Jacksonian epilepsies; meningitis and syphilitic dementia. In infancy, as a result of hereditary or intrauterine infection we see meningitis, convulsions, Little's disease and other forms of spastic paralysis; hydrocephalus, idiocy, imbecility, and other grades of mental defect, loss or injury to one or more of the special senses, and general arrest of development of the nervous system. In the post-tertiary period, from long continued activity of a low grade syphilitic process, the characteristic lesions are the so called parasyphilitic system degenerations illustrated by locomotor ataxia, spastic paralysis, the forms of combined sclerosis, together with general paresis, early senile dementia, and a large group of involutional psychoses which eventually help to fill our insane hospitals.

A long indictment, is it not? And it may all be summed up by repeating that almost all organic nervous disease is caused by syphilis.

I wish to insist now and always that these so called "nervous diseases," due to syphilis, are in essential character not nervous diseases at all—they are just syphilis. They should be recognized as syphilis, studied and discussed as syphilis, treated as syphilis; and they should, above all things, be divested of the mystery which seems inseparable from nervous diseases, leading us to regard them as peculiar or of special character, tempting us to group them in a class apart from the more material bodily ailments, and endowing them with some occult quality which requires special neurological skill for their elucidation, and demands the attention of a nerve specialist—and which likewise enables us to shift the blame for their unfavorable outcome upon neurology and the neurologists.

I am here reminded of the remark made some years ago by a more or less distinguished member of the medical profession who facetiously decried the specialty of neurology because all it could do was to "give iodides and an unfavorable prognosis."

*Read as a part of the symposium on syphilis, held at the meeting of the Medical Association of the State of Alabama, Mobile, April 18-21, 1916.

His personal experience doubtless justified the opinion expressed, for he never in his life called a neurological consultant until he was sure that the case was incurable.

In behalf of the neurologists I refuse to be held accountable for the hopelessly unfavorable end results of the uncured and sometimes undiagnosed syphilis which, on its way to the undertaker, passes through the neurologists' hands.

We general practitioners, surgeons, genitourinary and other specialists always treat syphilis ourselves, even though the nervous system is involved, just so long as we think the patient has a chance to get well. Should we become convinced that the case is incurable and the patient permanently paralyzed, insane, or going to die, we tell him that we now suspect that he is suffering from a nervous disease, that we have never been interested in nervous diseases, know nothing about them, etc., and advise him to see a nerve specialist, or we tell his family to send him to an insane asylum.

The neurologists sign the death certificates of some of these, and the insane hospital cemeteries receive the mortal remains of many others. But the fault lies at the door of neither neurology nor psychiatry. The fault rests upon the fact that we have not yet learned to cure syphilis.

When we cure syphilis in its early and curable stage, we will at one stroke wipe out the entire long and pitiful array of syphilitic nervous diseases. In no other way and at no other time can these diseases be cured. The entire subject should be dealt with as a public health problem—in no other way can it be effectively solved.

Let us face the situation as it is and make our patients and the public generally face it with us. Let us teach that these "nervous diseases" are simply syphilis and should no longer be buried and forgotten in hospitals for the insane and in neurological sanatoriums. Let us see that these diseases are brought into the light of day, stripped of the polite covering given them by the nomenclature employed in the textbooks, and made to stand forth naked as syphilis, because they are syphilis.

Let us teach our patients and the public also that, while they are, after the stage of full development is reached, as hopelessly incurable as any class of diseases known, they are all curable in their early stages and all absolutely preventable. As a class they represent merely the unfortunate residue, the unfavorable end results of imperfectly treated or of unrecognized syphilis.

Having once attained this point of view regarding syphilis of the nervous system in general, and regarding the parasyphilitic system degenerations in particular, to some extent we lose our active interest in the question of whether salvarsan is better than the iodides in spastic paralysis; whether the Ogilvie or Swift-Ellis procedure is to be preferred in locomotor ataxia; whether the injection of salvarsanized serum into the lateral ventricles through a trephine opening is justifiable in general paresis, and in the problem of whether mercury is best introduced with the hypodermic needle, swallowed, or rubbed on, for all of these methods of treatment, used after the nerve cells have been damaged beyond repair, eventuate in the same unfavorable outcome.

We read and hear and participate in long dissertations and discussions of them and of their relative desirability as therapeutic measures, and we feel greater or less interest in trying out and proving them. But when the kernel of truth is extracted from its shell of optimistic words, how many instances of real cure of any of the parasyphilitic degenerative diseases remain? None. Which leads me to say again that the time to treat and to cure syphilis of the nervous system is in its incipient stages before, not after, the poison has irretrievably damaged the neurons. This introduces the one other point which I would emphasize, and that is the great importance of making an early diagnosis.

Now it is fortunately true that oncoming nervous disease of syphilitic etiology casts its shadow before—a long shadow of premonitory signs and symptoms, recognizable by one who will take the trouble to look, which, in turn, suggests that our more familiar methods of physical examination should, as a matter of routine, be supplemented by the simpler procedures of neurodiagnosis. The discovery of any departure from the normal in motility, sensibility, the reflexes, the trophic, vasomotor, or mental functions should insure repeated and more comprehensive examination, with possibly a Wassermann test of the blood or spinal fluid. The habit of attention to the condition of the nervous system is a good one for a diagnostician to acquire and brings its frequent reward in the discovery of uncured or even unsuspected syphilis.

Even in the group of parasyphilitic degenerations so often referred to as hopelessly incurable in their typical and late stages, we should remember that the development of the characteristic clinical picture is a matter of slow growth, and preceded by a distinct prodromal period of long duration, during which symptoms of nervous syphilis are present, together with a positive Wassermann. The proper time to diagnose locomotor ataxia, for instance, is not after the patient becomes a typical case for demonstration to a class of medical students, but during the preataxic stage of fugitive rheumatoid pains, inconspicuous sensory dulling, and early disorder of the pupillary reflex. The best time to diagnose general paresis is during the preparetic stage of psychasthenia, which is so often present for months or years before the patient becomes a fit subject for the insane hospital. It will simplify the whole matter if we assume that any symptom of organic disease of the nervous system is evidence of an antecedent syphilitic infection until the contrary is proved.

As a contribution toward facilitating the recognition of involvement of the nervous system in the syphilitic process in its early as well as late stages, I would remind my readers of the following:

1. The neurasthenia syndrome is often present as the earliest evidence of cerebral or meningeal syphilis involving the convexity.

2. The psychasthenia syndrome likewise gives early warning of a diffuse syphilis cerebri affecting the vertex. The occurrence of either of these forms of neurosis in one who has had syphilis indicates danger of subsequent general paresis.

3. Ptosis and other oculomotor palsies are usually diagnostic of meningeal syphilis of the base.

4. Most atrophy of the optic nerve is syphilitic in etiology.

5. Many headaches and neuralgias are caused by syphilis.

6. Most of the pupillary light reflex abnormalities seen are of syphilitic etiology.

7. Chronic neuritis of sensory type is usually syphilitic.

8. Symptoms of spinal sensory root irritation—stabbing pains, anesthesia, disorder of position sense, delay in rate of transmission of nervous impulses, etc., are usually symptoms of syphilitic disease.

9. The onset of epilepsy after the age of thirty-five years means a syphilitic infection.

10. The occurrence of arteriosclerosis, cerebral hemorrhage, softening, etc., before the age of thirty-five years, is seen only in those previously infected by syphilis.

11. Nearly all spastic paralysis is syphilitic in origin.

12. Nearly all disturbances in gait are due to syphilis.

13. Most aphasia and other speech defects in adults are due to syphilis.

14. Most of the abnormalities of the deep reflexes, with the exception of those seen in acute nonspecific infectious diseases, are evidences of syphilis.

15. A large percentage of the cases of acute and chronic mental diseases are primarily syphilitic in causation.

In short, and to repeat still another time, practically all organic nervous disease is due to syphilis, and all symptoms of organic nervous disease are symptoms of syphilis. Let me say again that some of these symptoms are present and discoverable upon examination weeks, months, and years before the typical clinical picture of any form of "nervous disease" is produced. The nerve cells endure toxemic irritation for a long time before they give up the fight, degenerate, and die—and during this irritative, prodromal, preataxic, preparetic, preparalytic, prearteriosclerotic period nervous syphilis is curable. It is at this time that the Swift-Ellis, Ogilvie, and other salvarsanized serum injections should be used. It is at this period that mercurialized serum may do good. It is at this stage that mercury in any form, and even the much abused iodides, are useful and may be given with a favorable prognosis.

In closing I sum up this paper in three sentences:

1. Syphilis of the nervous system is syphilis and not a nervous disease.

2. Syphilis of the nervous system is recognizable by examination in its early stages.

3. Syphilis of the nervous system is, during its early stages, curable by any and all measures which will cure syphilis. In its later stages, after the death of the nerve cells, it is incurable by any means whatsoever.

Fermented Milk in Infant Feeding.—Albert E. Mucklow (*Medical Record*, June 24, 1916) is enthusiastic over feeding with certified milk modified and fermented with Bulgarian bacilli.

VERTIGO AND SEASICKNESS.

Their Relation to the Ear,

By Lewis Fisher, M. D.,
Philadelphia;
And Isaac H. Jones, M. D.,
Philadelphia.

Perhaps in the whole domain of medicine there is no subject which seems so vague and chaotic as that of vertigo. Doctors repeatedly speak in a general and indefinite way of "intestinal" or "stomach" vertigo, of vertigo from Bright's disease, dizzy spells from refractive errors, from indigestion, or neurasthenia, etc., without thinking even for a moment of the real mechanism of its production.

The most recent work on the ear makes it clear that vertigo is not some general manifestation accompanying disorders in this, that, or other organ, but that it is a peculiar and definite disturbance perceived within the brain itself just as sight and hearing are perceived in the brain, and that the vertigo impulses are transmitted thereto through the vestibular portion of the ear and its associated paths. Since the ear and its nerve paths are responsible for the production of vertigo, it might be profitable to refer briefly to a few absolutely essential facts relative to the physiology and anatomy of the internal ear or labyrinth.

The inner ear consists of two distinct organs, both housed in the same cavity: 1. A cochlear portion which attends to the function of hearing; 2, a vestibular or static portion with *equilibration* for its function. The static labyrinth consists of a saccule, utricle, and three semicircular canals. The saccule presides over linear movements in a lateral direction, the utricle recognizes linear movement in an anteroposterior direction, and the semicircular canals control rotary or turning movements in all conceivable planes. It is particularly important that the relation of the three semicircular canals to these planes be borne in mind in a discussion of vertigo. The semicircular canals have each a bulbous swelling on one end in which is placed a group of sensitive hair cells, capable of excitation. The eighth cranial nerve or "auditory" nerve, so called, conveys impulses from the whole labyrinth, and consists of two distinct parts—the cochlear which carries fibres of audition, and another distinct vestibular portion which carries fibres of equilibration. When this combined bundle, or eighth nerve, reaches the brain stem, it breaks up into its two component parts, the cochlear portion going one way and the vestibular going another.

The normal human organism depends in a great measure upon certain special senses, such as sight, taste, hearing, olfaction, etc. Among those is one, not generally known as a distinct special sense, but yet existing and of the utmost importance, namely, the static sense, i. e., a special sense whereby we are enabled to maintain our proper position in space. To those unfamiliar with this fact, we might point out the following:

Every "special sense" consists of three distinct elemental portions: 1, An "end organ" for perceiving external stimuli; 2, a brain centre for interpreting those stimuli, and, 3, nerve paths connecting the

two. Now this static sense is constructed on the same plan. It has an "end organ," the static labyrinth, in which are situated the hair cells capable of excitation. It also has a brain centre, postulated by Mills to be situated in the posterior portion of the temporal lobes. It likewise has nerve paths connecting the labyrinth with these centres. These paths are many in number and are most intimately associated with the cerebellum, the other special sense centres, and in fact with the whole central nervous system.

Perfect equilibration is accomplished through a harmonious cooperation of several special senses, chiefly the static sense, sight, and muscle sense. Disturbance of any one of them will result in partial or complete loss of equilibrium; but the point to remember is, that the static labyrinth, unlike the others, has equilibration for its *sole* function, and is the most important organ for the maintenance of balance and of orientation. *Any disturbance of the mechanism of equilibration induces vertigo.*

By vertigo we mean a subjective sensation of a disturbed relationship of one's own body to surrounding objects in space. That the labyrinth was a factor in maintaining the equilibrium of the body was suspected by numerous observers for many years. But it was not until 1860 that this relationship was established as a clinical entity. In that year Menière, of Paris, published his epoch making paper, in which he described that train of symptoms always referred to thereafter as Menière's disease. Many others followed him and made contributions to the subject, but no work has equaled the recent brilliant efforts of Dr. Robert Barany, of Vienna. That his work upon the physiology of the labyrinth was of more than passing interest was attested to by his receiving recently the Nobel Prize, awarded annually for research work in medicine. He has established, beyond doubt, that the static labyrinth constitutes the chief organ of equilibration. It accomplishes this by being most intimately connected through the central nervous system with nearly every portion of the human organism. The nerves connecting this vestibular portion of the labyrinth with the rest of the body may be spoken of as the vestibular paths or tracts. Stimulation, or irritation, or destruction of the labyrinth, or of any portion of the vestibular tracts, induces vertigo or dizziness with associated loss of equilibration. We must not be misunderstood as meaning that irritation of the ear itself is the sole and only way of producing vertigo. We all know that various visual disturbances, cardiovascular affections, gastric or alimentary disorders, etc., may exhibit vertigo as a symptom. What we do wish to impress, is that in the latter instances it is their direct action on the *vestibular apparatus* that is responsible for the induction of the vertigo. The stomach of itself, or the kidneys, or the heart, etc., can no more produce vertigo, than they can produce sensations of flashes of light, hallucinations of sound, or obsessions of smell. It is generally known and admitted, as a matter of course, that the light, sound, and smell sensations in these instances are produced by irritation or stimulation of the visual, auditory, or olfactory apparatus as the case may be. Just in the same way, when disease in any of the organs just mentioned is accompanied by vertigo, it is due to a direct effect on the static organ or its distribution. Should the same pathological states for one reason or another fail to irritate the vestibular tracts, *there will be no vertigo.*

Vertigo produced by inflammatory or other conditions of the ear itself can be differentiated from other kinds of vertigo by an examination of the ear. By this we have come to mean, not only the study of the hearing function, but a careful investigation of the static portion of the labyrinth as well. When attempting to determine the origin and nature of vertiginous attacks, so that an intelligent prognosis can be given and proper treatment instituted, it is absolutely essential to determine the functional activity of *every* portion of the inner ear. The acoustic labyrinth is therefore carefully tested by means of tuning forks, while the static labyrinth is examined most scrupulously by the new labyrinthine tests. These tests enable us to determine the functional value of the various portions of the inner ear, and also to demonstrate any affection or interference with the vestibular paths connecting the labyrinths with the central nervous system. Many of these vestibular paths are well known and definitely located. Clinically this knowledge is of the greatest interest and importance as we are enabled by means of these tests to locate with a good deal of accuracy lesions within the cranium, particularly so if they happen to involve those paths themselves. The importance of it has been recognized to the extent that at a number of our local leading teaching institutions, beginning with the University of Pennsylvania and followed by the Medico-Chirurgical College, special subdivisions of their respective ear departments were created, where all patients complaining of vertigo or suspected of an intracranial lesion are carefully tested out in this way with a view of determining the integrity of the labyrinths and the associated paths. These vertiginous cases are sent to the ear dispensaries from *all* the departments, chiefly the medical and nervous, to which many of the patients first apply for relief.

As these labyrinthine tests are new we might say a few words about them. The principle underlying them all is this: Movement of the endolymph in the semicircular canals in a given direction, stimulates the sensitive hair cells in these canals, and produces definite phenomena. These phenomena are: 1, A twitching of the eyes or nystagmus of a certain type; 2, vertigo; 3, so called "past pointing"; 4, falling reactions. In a person to be examined this endolymph is artificially set in motion, either by turning the subject in a smoothly revolving chair, or by douching the ear with cold or hot water. The reactions following are carefully observed. With a knowledge of what these reactions should be *in the normal*, and knowing furthermore that in a normal individual they are remarkably uniform and constantly present, we are able to recognize that any deviation from the normal, or a complete absence of some or all of the reactions, is significant of a disturbance either in the labyrinth or somewhere along the vestibular tracts. In this paper we will speak only of that reaction which is immediately under discussion, namely, vertigo.

If a person is turned toward the right, with the head in the upright position, with the eyes closed, his first sensation is that of turning toward the right. This is due to the lagging behind of the endolymph in the horizontal semicircular canals. As the turning is continued the endolymph catches up to the movement of the body, and the subject no longer feels that he is turning, although actually he *is* turning. On stopping the chair the endolymph continues to move and the person has the sensation of turning in the opposite direction, namely, to the left, although as a matter of fact he is sitting absolutely quiet in the chair. This induced vertigo, or what we may call experimental vertigo, is obviously produced by setting in motion the endolymph in the labyrinth.

Experimental or vestibular vertigo manifests itself in certain definite planes.

1. Sensation of turning in a horizontal plane, either from the right to left or from the left to the right.

2. Sensation of turning in the frontal plane or rather the sensation of *falling* to the right or falling to the left.

3. Sensation of turning in the sagittal plane, or rather the sensation of pitching forward or backward.

Sensation of movement in the horizontal plane is produced by horizontal canal or canals only. This is experienced by the subject when he is turned with the head in an upright position.

The sensation of turning in the frontal plane is produced only when the vertical canals are influenced in that plane. This can be produced in a subject by turning him with the head placed forward or backward, in which position the plane of the head is frontal. If, after such turning, the head is permitted to remain in the forward or backward position, the sensation that the subject experiences is one of turning in the frontal plane, which in this position of the head is parallel to the floor. The sensation is therefore the same he experienced after being turned with the head upright, namely, a movement about his own axis, either to the right or to the left. As it is a sensation of turning in a plane parallel to the floor, or the horizontal, it is not unpleasant. If, however, the head is then raised to the upright position, the frontal plane now assumes a position at right angles to the floor, and the subject has a sensation of falling either to the right or to the left, which is therefore unpleasant.

The sensation of turning in the sagittal plane is produced only when the vertical canals are influenced in that plane. If a subject is placed in a chair with the head inclined well over toward the shoulder, his head is then in the sagittal plane. If he is turned now with the head in that position, the resulting subjective sensation is one of turning in that same sagittal plane, which, however (in this position of the head), is parallel to the floor. The sensation is therefore the same as that experienced after being turned with the head upright, namely, a movement about one's own axis either to the right or to the left. As it is a sensation of turning in a plane parallel to the floor, it is not unpleasant. If, however, after such turning, the head is raised to the upright position, the sagittal plane assumes a position at right angles to the floor, and the sensation is that of falling in the sagittal plane, namely, pitching forward or backward. This is unpleasant.

In connection with unpleasantness from these turning sensations, we may consider seasickness. *Mal de mer* is unquestionably an *ear* phenomenon. As Barany[1] has stated, the reason that this is not generally recognized is that the phenomena of the labyrinth and the vestibular apparatus are not generally understood. In 1881, Champeaux first showed the close similarity between Menière's disease and seasickness. In both conditions there is an aura consisting of a sensation of flashes of color before the eyes, and a breaking out of sweat; there is vomiting of a projectile type, which occurs very easily and produces only temporary relief. In both instances the sufferer feels worse on attempting to stand or move about and shows distinct ataxia; lying down and closing the eyes usually results in some relief. Headache is present in both instances and occasionally there is a nervous diarrhea after the vomiting.

Deaf and dumb people do not become seasick. This was first brought out by W. James. Similar proof of the relation of the ear to seasickness was proved experimentally by Kreidl. He constructed a floor on which he rocked animals, indicating the movement of a ship at sea. He was able to make the animals sick in this way. He then operated on the animals and severed both *eighth nerves*. When they recovered he conducted the same experiment and found that they could not be made seasick again.

Trotsenberg makes the observation that in very small children seasickness is uncommon, bringing out the fact at the same time that douching the ear with cold water in children similarly fails to produce nausea. This could be explained by the fact that the vestibular apparatus of small children, not yet being highly developed, shows but little response either to the movement of the ship or to experimental stimulation of the ear by douching.

Ruttin had the same idea as to the causation of *mal de mer*, and to prove it he performed the following experiment on himself. He went out to sea purposely to make himself seasick, and when in that condition he had a colleague of his, Doctor Beck, douche cold water in both of his ears simultaneously with an apparatus which he had devised. This produced a decided lessening of his seasickness. Unfortunately for therapeutic purposes the relief lasted only so long as the douching was kept up.

Barany has shown that persons who show no response to stimulation of their ears experimentally cannot be made seasick. This is substantiated by our own experience with patients who have "dead" or nonreacting labyrinths. Barany also brings out the following interesting facts: Persons who by stimulation of the ears become easily nauseated also become seasick easily. Neurasthenics are sensitive to being turned in a chair or having their ears douched, and they also become seasick easily. Persons who become seasick from certain movements of the boat, also become seasick by the very same kind of vestibular stimulation. The manner of onset and the persistency of the nausea are the same in

[1] Seekrankkeit, *Handbuch der Neurologie*, 1912. This paragraph is largely based on this article.

seasickness as in experimental vestibular stimulation. Furthermore, the sensations after seasickness are the same that we have after being nauseated by violent vestibular stimulation. Any means which would help against seasickness, such as altering the position of the head, helps as much against the unpleasant sensations experienced when one is being turned in a chair. After getting back to land the seasick person quickly becomes perfectly normal again; in the same way nausea produced by violent vestibular tests quickly disappears.

Seasickness is therefore an ear phenomenon, by which we mean that the end organ of equilibrium, namely, the static labyrinth, is disturbed by the unaccustomed movement of the boat or ship. The tossing of a ship may be analyzed as movements in the following planes:

1. *The horizontal plane* from right to left and from left to right. This movement, however, is usually very slight, and unfortunately, as we have already shown, it is the only plane of movement that is not unpleasant.

2. *The frontal plane,* namely the rolling of the ship from side to side. If the subject is standing facing the bow of the ship, such a movement will influence the vertical semicircular canals in the frontal plane. Such stimulation is unpleasant. If, therefore, the subject *lies down* with his head toward the bow or stern, the rolling movement would then affect the *horizontal* canals and the unpleasantness would disappear.

3. *The sagittal plane*, namely, a pitching of the ship fore and aft. If the subject is standing facing the bow of the ship, such a movement affects the vertical semicircular canals in the sagittal plane. The resulting sensation is extremely unpleasant. If, however, the subject lies down with the line of the body extending across the ship from starboard to port, then the pitching movement affects the horizontal canals instead of the vertical and the unpleasantness disappears.

The up and down movement of the ship, that is, the rising and the sinking, in a similar way affects the vertical semicircular canals when the subject is in an upright position. The resulting unpleasantness is again relieved by the subject lying down, since then the up and down movements affect the horizontal canals instead of the vertical, the stimulation of which is so much less unpleasant. Unfortunately the movement of the ship seldom takes place *in one plane only*. It is the *combination* of the various planes which plays havoc with the semicircular canals.

In consideration of these facts, to speak of the role that the ear and the ultimate tracts play in the production of vertigo, is like speaking of the role the heart plays in the production of cardiac murmurs. A normal static labyrinth and vestibular mechanism see to it that we have no vertigo. They accomplish this by keeping the central nervous system continuously informed of our position in space with relation to objects around us. In the presence, however, of some pathological condition in the labyrinth or along any of its paths, the perfect performance of this function is no longer possible. Objects around us do not appear as they should. They either move or dance before us. Our own bodies feel no longer stable and secure upon the ground—in other words, we are *dizzy* or are experiencing sensations of vertigo which, if serious enough, result in our inability to move about or stand upright.

Summing up, then, all vertigo of whatever cause, be it from stomach, kidneys, eyes, or what not, is directly due to a disturbance along some part of the vestibular paths. The pathological conditions that may affect the labyrinth itself are of course legion and cannot be discussed in a paper of this character. For our purposes it is best to limit ourselves to certain general principles. Among the things to bear in mind is this, namely, that the static labyrinths always act in unison. They continuously keep sending out an equal flow of tonic impulses to the whole body, the right labyrinth as much as the left, and the left labyrinth as much as the right. When, however, a pathological process impairs or exaggerates the action of one of the labyrinths, there results a definite disturbance of this nicely adjusted mechanism with vertigo as a symptom. Impairment or stimulation of both sides to exactly the same extent produces no vertigo whatever. Diseased conditions within the ear itself may produce vertigo in the following ways: 1. By an actual impairment or destruction of the static end organ in the labyrinth itself; 2, by affecting the circulation and pressure in and about the labyrinth, resulting in an abnormal stimulation of the labyrinth hair cells.

Inflammatory conditions of the middle ear, for instance acute otitis media, or mild inflammations of the inner ear itself, produce only irritative effects, if any, so that the patients suffer from more or less vertigo as long as the acute stage of the congestion lasts, the vertigo vanishing with the disappearance of the inflammation. On the other hand, slow degenerative changes of the labyrinth, or sudden destruction of the whole or part of one labyrinth, are accompanied by *marked vertigo,* nausea and vomiting, and loss of equilibration. Such slow degenerative changes are seen in syphilis, diabetes, gout, lead poisoning, and other systemic affections.

Sudden destruction of the whole or part of the labyrinth may be produced rarely by trauma, but usually by hemorrhage or serous effusion into it, and may occur in diabetes, Bright's disease, or in any condition where the vascular system becomes affected. It is this class of cases that exhibit the so called Menière's symptom complex. The hearing in these patients is usually markedly affected if not altogether gone, and the condition is characterized by repeated attacks, with a suddenness of onset, the violence of the symptoms quickly reaching a climax and then gradually subsiding, and all of it disappearing when the brain centres have learned to compensate.

In conclusion we should like to emphasize the following:

1. Vertigo from whatever cause is a disturbance of the vestibular apparatus.

2. Disturbance of the vestibular apparatus can be definitely analyzed by means of the new ear tests.

3. Cases of vertigo, therefore, need no longer be regarded as vague or mysterious, but should be cleared up by means of the ear tests.

BONE SETTING AND ITS MODERN REVIVAL.*

By Norman D. Mattison, M. D.,
New York.

There is probably no practice having to do with the healing art which has been more neglected by the profession, and more opposed by it for lack of understanding, than the olden art of so called bone setting. It has been from its inception a practice based mainly on experience rather than research, and therefore empiric. So far as available references show, no effort has been made to record its interesting history, and at the same time to trace its evolution and its development into the present day practices of manual therapy.

It is the purpose of this paper briefly to review the bibliography of this practice, to prove by deduction that the old empiric practice of bone setting and the present day practice of manual therapy, known as osteopathy, are one and the same as to their basic principles, and finally to draw some conclusions. So far as may be determined, no previous attempt has been made to prove this proposition, with the exception of a brief suggestion as to the analogy, by Bryce (1) in the *British Medical Journal* a few years ago. Within the scope of this paper will be considered seriatim the available essays here and in England, to point out the analogy of bone setting to its present day revivals in osteopathy and chiropractic, to propose the correct status of these latter practices by promoting a better understanding of their evolution, and finally to comment on the fact that manual therapy may in time find its rightful place as a legitimate specialty in the broad field of therapeutics. The literature of bone setting is by no means replete, and much more of moment has been written by the regular profession abroad regarding it than has appeared in the medical journals of this country.

BONE SETTING IN AMERICA.

The old practice of bone setting in America has been closely associated with the family of Sweet for more than two hundred and fifty years. Among the apparently few biographers of the Sweet family are Comstock (2) and Wilder (3, 4). It is recorded that James Sweet emigrated from Wales and settled in Rhode Island in the year 1650. All his descendants appear to have been endowed with, or to have attained in greater or less degree his same peculiar and unusual ability in the treatment of many difficult cases. A number of these are recorded; though the articles of these writers are mainly biographical in character, and little of technical value may be adduced from them. To quote from Wilder: "Whether they (the Sweets) alone possessed the peculiar skill, it is too much to say. Doctor Kittredge, of New Hampshire, exhibited similar talent and appears to have been in many respects like them. Their mode of procedure has been learned by others who did not scruple to proclaim it as their own discovery."

One of the few notable cases recorded in our medical journals, and one the pathology and treatment of which served as a topic of considerable discussion at the time, is reviewed by Ziegler (5). The case was one of a supposed dislocation of the hip joint of more than twenty years' standing, which condition was corrected in a manual operation by an Italian bone setter, Dal Cin. Though Ziegler did not witness the operation, his article is valuable because it presents an interesting academic discussion, based on the details of the case as they were known to him.

ABSTRACTS OF ENGLISH CONTRIBUTIONS.

Probably the first authoritative essay on this subject, whereby the attention of the profession in England was directed to it, was that of Sir James Paget (6) in a clinical lecture at St. Bartholomew's Hospital, London, in 866. In this lecture, supplementing his course on the injuries of bones and joints, Paget considered the conditions which may be amenable to treatment by bone setters; though he asserted that "the surgeon with his discernment of appropriate cases, and guided by a better diagnosis than the bone setter can ever make, may treat these cases more safely and as successfully with comparative gentleness." The analysis of cases usually treated by bone setters is apparently the first systematic effort to define the practice, and forms at least a partial basis of the work of Hood, next to be reviewed, and for which due credit was given.

About four years after Paget's lecture there appeared what is probably the first authoritative monograph by one of the medical profession, based on a working knowledge of this practice. Prompted by an interest in the subject, and with a desire to report his conclusions to the profession, Hood (7) studied and later applied in many cases the methods used by Mr. Hutton, of Watford, one of the best known bone setters of that time. The practice was defined by Hood as "the art of overcoming by sudden flexion or extension, any impediments to the free motion of joints that may be left behind after the subsidence of the early symptoms of disease or injury; perhaps more frequently of the latter than the former."

The class of cases which he concluded to be amenable to treatment may be summarized as follows: 1, Stiffness of joints following fracture; 2, sprains, whether recent or old, which had been treated by enforced rest; 3, joints which had been kept at rest after intraarticular or extraarticular injury or disease; 4, rheumatic or gouty joints; 5, displaced cartilages; 6, ganglionic swellings about the carpus; 7, subluxations of bones of the carpus and tarsus; 8, displaced tendons; and, 9, hysterical joints. The cases most successfully treated were those "in which some restraint of movement, due either to an injury or the rest consequent upon it, or to both together, and which painfully checks the motion of the joint, admits of being at once overcome by manipulation."

Although broadened surgical experience has added much to the knowledge of bone and joint pathology since that earlier epoch, Hood gave an interesting explanation of tissue changes in the conditions treated by these methods. Among the joint changes described in intraarticular inflammation were the formation of adventitious bands and adhe-

*Read before the National Society of Physical Therapeutics, Baltimore, June, 1916.

sions between apposed surfaces, due to a synovitis of the reflected folds of membrane. The results of extraarticular changes were described as adventitious bands and adhesions from effusions following sprains and injuries, suppurations of bursæ and of deep fasciæ, rigid or adherent ligaments and shortened muscles as sequelæ or coincidents, and lastly, to the lessened joint secretions due to continued rest and an absence of the normal stimulation of joint movement, both in the articulations and in the tendon sheaths. The technic of manipulation was applied not only to the long bones of the extremities, but to the vertebræ as well. "The first step is to feel all around the affected joint for a spot that is painful on pressure, . . . the force is applied suddenly and in a perfectly definite way, for the attainment of a definite end, and ceases as soon as that end is arrived at." This much is a summary of the salient points of Hood's monograph.

FURTHER OBSERVATIONS OF ENGLISH SURGEONS.

Marsh (8) later reviewed in detail a series of joint cases treated by manipulation under general anesthesia, and also recorded a number of cases treated by bone setters which had come to his attention. Like his two confrères already quoted, he based his conclusions on a sound bone and joint pathology, and rejected the principle of the bone which is "out." To quote from this writer, ". . . the loud snap which is often heard when a joint which has long been stiff or at rest is suddenly moved is a phenomenon to which bone setters point as a plain demonstration that a bone was out and had been put in. . . . These snaps, however, are not produced by the concussion of two joint surfaces as they come suddenly into contact, but, on the contrary, are due to the sudden separation of two surfaces which have been stuck together by a too viscid and tenacious fluid." Further: "They (the surgeons) look with little favor on the practice of wrenching; and if after using it they find the patient though benefited yet not cured, they are so lukewarm in the matter as not to repeat the proceeding, but instead rest and are thankful that no harm has followed the first venture; while, under similar circumstances, the bone setter, who is nothing if not manipulative, and who asserts that the bone is so badly out that it must be "put in twice," goes boldly on and cures the patient. . . . We cannot look with indifference on either their successes or their failures, for their successes prove that we have been remiss, while for their failures . . . we are in no small degree responsible, if by neglecting the manipulative treatment we encourage or even compel patients to seek their help." A further series of cases of bone setting was later presented by Marsh (9) before the Clinical Society of London, and the report of the extended discussion is an earnest of the interest taken in the subject at that time.

Bruce-Clark (10), during his service at St. Bartholomew's Hospital, applied this mode of treatment in many cases, some of which he reported before the Abernethian Society. Details are given of two specimens examined after amputation, in which the joints were healthy, but between the tendons and tendon sheaths of which were numerous bands of adhesions, so that their motion was exceedingly limited. This he attributed to organized effusion, much the same as the effusion in pleurisy. In the treatment of his cases he concluded that by forcible movement, tension on the adhesions and contiguous tissues was increased and pain was thereby induced. Further, that the pain was relieved with the rupture of the adhesions, this latter giving rise to the usual cracking sound. In conclusion, he alluded to cricks of the neck and other conditions affecting the vertebral column which come so often under the hands of the bone setter.

The first time the subject of bone setting was presented before the British Medical Association was in a paper contributed by Fox (11), in 1882. The author at that time was associated in the surgical practice of Mr. James Taylor, of Whitford, in Lancashire, the latter the last descendant of a family, each one of which was a qualified surgeon, who had practised bone setting in Lancashire for more than two hundred years. The class of cases which Fox concluded to be amenable to treatment were: 1. Joints which had become stiff through enforced rest or chronic disease; 2, joints stiff from injury to the bones entering into their formation; and, 3, joints stiff and weak from sprains. He attributed at least some of the indisputable success of the bone setters to the carelessness or indifference of the general body of practitioners in overlooking minor joint injuries.

A later contribution is that of Mansell-Moullin (12), who, like each of his surgeon confrères, discussed the subject with a desirable knowledge of applied anatomy and of sound surgical principles. His paper is of interest as supplementing the earlier essays which have been reviewed.

The writings of these English surgeons have been abstracted to show, not only the evolution of present day practices in America, but as well to point out the interest manifested in the subject of bone setting in England. In their contributions they desired to present to the profession the results of their own application of the principles of bone setting in selected cases, and at the same time they attempted to define the limitations of the practice.

SWEET, THE BONE SETTER, AND STILL, THE OSTEOPATH.

While the monograph of Hood is probably the most complete essay written by a member of the medical profession, the most comprehensive work from the standpoint of the bone setter himself is the autobiography of Mr. Waterman Sweet (13), published in 1844. It is evidently a little known work, as no reference to it has been found in a review of writings on this subject. The apparent aim of Sweet's work was to leave something of record for those who might succeed him, in order that "it might enable them to be useful to their fellow creatures throughout time." His attitude toward the regular profession, despite the fact that many times he had been roundly opposed, was one of kindliness rather than antipathy; nor did he wish to speak against medical aid.

The purpose of reference to this work of Sweet's is to point out an analogy, of interest because it

serves to promote a better understanding by the profession as to the status of at least one of the modern adaptations of bone setting. W. Sweet, the bone setter, began his career in Rhode Island about 1790, and published his autobiography in 1844; A. T. Still (14), the first exponent of osteopathy, began his work in Missouri in 1874, and published his autobiography in 1897. There is a striking similarity in the context of the works of Sweet and Still; though it is not unusual that two men, widely separate as to time and distance, should arrive at conclusions so nearly identical as the following excerpts from their respective writings disclose:

SWEET	STILL.
. . . to sustain my claims to eminence in the sciences of intuitive and self taught surgery and anatomy.	I suppose I am the oldest osteopath now on earth. I also think I have given more attention to the study of the principles of this science than all persons now living combined.
. . . from an early day . . . I had a predilection for the study of anatomy . . . I have made anatomy, or bone setting, my constant study and practice for fifty years.	The bones . . . was always a study to me, long before I learned (their) names. . . . When I commenced this study I took the human bones and handled them for twelve months.
It (the human body) is so complicated a machine.	. . . osteopathy is a science built upon the principle that man is a machine.
. . . to notice the actions of all the parts which constitute the human body in its different bearings and circulations, and the difficulties that obstruct the fluids, depress the circulation, and cause pain, soreness, debility, and diseases of limbs.	This year (1874) I began a more extended study of the drive wheels, pinions, cups, arms, and shafts of life, with their forces and supplies, framework, attachments, muscles, . . . blood supply to and from the heart, . . . voluntary and involuntary nerves . . . in the obstructing parts . . . through which they passed . . . to perform their part in the function of life.
. . . practice of . . . cases of almost every description.	. . . treating many kinds of diseases.
. . . no book ever published has ever given me the least knowledge of anatomy in bone setting.	Before I ever studied anatomy from books I had almost perfected the knowledge from the great book of nature.
. . . it (bone setting) is not . . . from books . . . but obtained by practice and observation.	Osteopathy cannot be imparted by books. . . . a treatise . . . would be worse than useless to every person who had not been carefully drilled in our clinics.
As the blood is the life, it is the principle of the (human) system. . . . a want of blood or its circulations, occasions in any part or limb, a drying up of the fluids and decline of the flesh in the part affected.	In the year 1874 I proclaimed that a disturbed artery marked the beginning to an hour when disease began to sow its seed of destruction in the human body. . . . I have been for fifty years fully established in the belief that the artery is the father of the river of life, health, and ease, and its muddy or impure water is first in all disease.
In cases of dislocation by accident, it brings a pressure or loosening of the nerves, which gives pain and soreness, or weakness, and debility, together with the disorganized state of the joints, blood, muscles, and tendons.	The cause (of disease) can be found and does exist in the limited and excited action of the nerves only which control the fluids of parts or the whole of the body.
The muscles, to which the ligaments are attached, . . . in some degree are all affected either in contractions or by being too slack, . . . until, by an operation, all the joints affected are replaced, and then all the fluids begin to flow and a natural conformity of all the parts takes place soon in new cases, and but slow in cases of long standing.	. . . normal does not mean simply to place bones in a normal position (but) that muscles and ligaments may play in their allotted places and can act with freedom at all times.

THE STATUS OF OSTEOPATHY.

The foregoing analogy has been carried out only to the extent of showing the concept of Sweet and Still to be practically identical; but it is no part of the purpose of this article to suggest that Still was familiar with the writings of Sweet. In fact, Still would seem to deny any knowledge of them. "I do not claim to be the author of this science of osteopathy. . . . I discovered it." (14). It may be questioned, however, if there could be an absolute discovery in a field of this nature, except by one totally unfamiliar with applied anatomy and therapeutic practice in connection with it; it has been said that "all the men who are now called discoverers in every matter ruled by thought, have been men versed in the minds of their predecessors, and learned in what had been before them. There is not one exception" (15).

It is a little known or a forgotten fact that the first school of osteopathy in its application for charter, which was granted by the State of Missouri, indicated the purposes of teaching the subjects usually taught in medical colleges, and of granting the degree usually conferred by them. This school has not included in the course a comprehensive training in materia medica and therapeutics, nor granted the medical degree. So far as the writer is informed, only one osteopathic school includes materia medica in its courses, and none of the schools confers the medical degree. The osteopathic schools continue as separate entities, not because lectures on the principles of bone setting and massage may not appropriately be included in the curriculum of medical colleges, but owing primarily to the inertia which customs and traditions of the medical profession induce—inertia rendered all the more fixed by the radical stand assumed by the first sponsor of osteopathy, and the extreme terms in which he stated his claims and principles of practice. He said: "If osteopathy is not complete within itself, it is nothing": and he also referred to allopathy, homeopathy, and eclecticism as "fading sciences of antiquity," with which osteopathy must not be belittled by association. This writer also asserted that "there is no such disease as fever, flux, diphtheria, typhus, typhoid, lung fever, or any other fever," and that

"rheumatism, sciatica, gout, liver diseases, . . . on to the end of the list. . . . do not exist as diseases." He is thus one of the few to deny the existence of disease as such since Asclepiades, more than two thousand years ago, advanced as a premise the principle of constricted and relaxed, tonic and atonic, sthenic and asthenic states of the body (16).

The traditions of this modern adaptation of bone setting, as well as the etiology and treatment, remain much the same as when Still reported his work and asserted: "The philosophy (of osteopathy) is eternally the same"(14). The dictum of this writer to "find it, fix it, and let it alone," referring to the subluxation or lesion, or the bone which is "out," bears another analogy to the technic of manipulation, to which previous reference was made from Hood's work. While osteopathy has always disdained any comparison to massage, the essentials of the osteopathic "soft tissue adjustment" may readily be found in an authoritative monograph on treatment by physical methods such as that of Dowse (17)—incidentally a work more comprehensive of the massage branch of manual therapy than any osteopathic text which has as yet appeared.

The regular profession during the last quarter century has witnessed the steady development of manual therapy, and in many States its regulation by legislative enactment; and during this time no constructive program has been successfully carried out to place it in its rightful position as a part of general medical practice, or rather as a specialty. There is nothing mystical about the principles and practice of mechanotherapy, and the statement made by Paget (6) fifty years ago, that appropriate cases may be treated as successfully by the regular practitioner applies with equal truth today. More recently Schreiber (18) advances this opinion: "The time was when reputable physicians scrupled to busy themselves with mechanical treatment; or, if they did, hesitated to commit to paper their ideas on the subject, or to contribute, by clinical observations, their mite toward spreading this now no longer new method of cure. That day happily is past, . . . and today the most eminent physicians do not for a moment hesitate personally to treat disease by manipulations."

CHIROPRACTIC BRIEFLY CONSIDERED.

There has been in this country, so far as I am aware, but one other adaptation of the general principles of practice underlying bone setting. It is believed that the ancient Bohemian empiric practice called napravit (to thrust) was the basis of the "discovery" in 1895 by Mr. Palmer, of Davenport, Iowa, out of which has been exploited the cult of chiropractic. Palmer was a man of no medical education, but this did not deter him, for, as an admirer unhesitatingly asserts, he succeeded in "wrenching from nature her secret"—the cause of all disease and the way to remove that cause. That he and his followers are not likely to attain this latter ambitious project may be deduced from the principles of this practice, thus defined in an official organ of the cult: "Chiropractic is a philosophy of biology, theology, health, disease, death, the cause of disease, and art of adjusting the relations between them to harmonious quantities and qualities, by hand, thus correcting all subluxations of the three hundred articulations of the human skeletal frame, more especially those of the spinal column, for the purpose of reestablishing the normal current through impinged nerves as they emanate through intervertebral foramina, which were formerly excessive or lacking, named disease. All movements, whether normal or abnormal, of, or in the body (including blood circulation) are but the personification of mental equivalents—mental functions guided by Innate Intelligence, creating physical expression. An ache or pain is but the Intellectual Inherent interpretation placed upon impressions received from the periphery, proving the abnormal physical conditions."

If further interest may be taken in this cult or in the school situated in its birthplace, wherein many of the exponents receive an elementary training, reference may be made to the reports of the inspector of the Pennsylvania Bureau of Medical Education and Licensure, and to the comments of Duhigg (19) on these reports.

CONCLUSIONS.

1. There is no reason why the general practitioner should not avail himself of such manipulative treatment as is of proved efficacy and success. Indeed, orthopedic practice has given an increasing dignity to the hand as a therapeutic agent in certain bone and joint conditions; the osteopath has made it popular as applied to all conditions, whether appropriate or not. The profession of medicine has neglected an opportunity, and the public has been the arbiter. Though I hesitate to advance an *ex cathedra* forecast, I believe the next decade will witness one of two conditions, perhaps both: the osteopathic school will become in reality a college of medicine and surgery, or the regular medical college will include mechanotherapy in its curriculum.

2. Within recent years renewed interest has been taken in the correlation of structural asymmetry to disturbances, not only of visceral function, but as well to the derangements of the joints composing the bony framework. The restoring of structural symmetry in the adult, and the acquiring of it in the child and adolescent, is a problem of body statics. The solution of this problem is a study of the mechanics of the entire structure, not of the individual joint or joints, unless there is, in the surgical sense, a local lesion.

3. Excluding gross dislocations, recent fractures, or pathological bone or joint changes, when the centre of motion of a joint or a number of joints is determined to be continuously altered, a knowledge and application of body statics is essential to restoring a joint or joints to a state of normal function. Whether the change is from extremes as varied as acute strain to fixed scoliosis, the problem is one of mass rather than the bony segment, and of the tractive forces rather than of the bones themselves.

4. Provided that consideration is given to all joints, the motion of which is directly or remotely affected, manipulative measures toward this end supply a desirable and necessary stimulus to the kinesthetic (muscle joint) sense, to the joint tissues, and

to the tissues on which the motion of the joint is dependent.

5. Bone is inert, and in movable joints has no inherent power to maintain normal motion, nor to resume it if this motion is altered. Hence, improvement both in the kinesthetic sense and sense of voluntary control, is the end toward which any measure of normalizing the joint is directed. Again excluding pathological bone and joint changes, manipulations directed toward restoring correct statics, supplemented by the direction of specific voluntary efforts on the part of the patient, have proved of definite value in many cases in which visceral function has not been corrected by remedies, and in joint function for which apparatus, retention, or operative measures are not indicated.

6. To the practitioner who specializes in manual therapy, or who uses manipulative measures in his practice, the field is a broad one for original work, provided that he avails himself of any and all helpful measures based on collateral experience.

TUBAL STERILIZATION.

Pregnancy Following Bilateral Salpingectomy, A Report of Two Cases and a Complete Review of the Literature,

By Alfred Heineberg, P. D., M. D.,
Philadelphia,

Associate in Gynecology, Jefferson College; Obstetrician, Jewish Maternity Hospital; Assistant Gynecologist, St. Agnes and Mount Sinai Hospitals.

It is not the intention of this paper to discuss the sociological, moral, or legal aspect of the problem of tubal sterilization, but the surgical phase only. The purpose of so doing is to emphasize the necessity for the selection of the surest and least objectionable method of producing sterility in the female, when once it has been decided that such a procedure is desirable. My interest in this subject was aroused by the occurrence of pregnancy in two patients in whom I performed bilateral salpingectomy for the relief of chronic inflammation. This unexpected sequel emphasized the fact that, if sterility had been the object sought, the operations would have had to be classed as failures. Pregnancy has unexpectedly occurred in many patients after operations upon the Fallopian tubes performed for the express purpose of producing sterility; and in others who were subjected to bilateral salpingectomy for the relief of tubal disease. The study of the operative methods employed in all reported instances of failure; a review of other methods proposed for tubal sterilization; and the consideration of the animal experimentation, should assist us in the selection of that method which promises the surest result. After a complete review of the literature, it has seemed to me that the following classification would be helpful.

Group I comprises all cases in which operations upon the Fallopian tubes failed to produce sterility. It includes those cases in which sterilization was the object sought and others in which, from the nature of the operation, sterility was to have been expected.

Group II includes cases in which a second operation upon the same patient demonstrated the failure of the first operation to occlude the tubes. In these cases no pregnancy had resulted, although there was no hindrance to its occurrence.

Group III includes cases in which operative methods, different from those used in Groups I and II, were employed for the production of sterility, but in which neither failure nor definite success was reported.

Group IV consists of the review of the experiments done upon animals to determine the value of several methods.

In the first group there are recorded twenty-five failures to produce sterility by the following procedures: A. Ten failures after simple ligation of both tubes. B. Three failures after double ligation and section or resection of the tube between the ligatures. C. One failure after crushing and ligation of both tubes. D. Eight failures after bilateral salpingectomy with ligation of the uterine stumps of the tubes. E. Three failures after bilateral salpingectomy with cuneiform resection of the uterine cornua.

Ligation of the tubes. With the exception of the three cases reported by Gordon (1) and Sutton (2), the reported failures which occurred before 1897 followed simple ligation of the tubes. The uncertainty of this method is attested by the following reports: In sixteen cases of vaginal fixation of the uterus performed by Arendt (3) in 1897 he ligated both tubes with silk or formalin catgut. In one case pregnancy soon followed. Fritsch (4) in 1897, during a laparotomy, ligated both tubes with silk. The patient became pregnant three years later. As a result of this experience he recommended double ligation with section of the tube, but found this to be no more effective. During a Cæsarean section, Pissemsky (5) in 1897 ligated both tubes with silk. The patient became pregnant again and was subjected to a second Cæsarean operation, during which both tubes were removed. He found one tube patulous, the other closed and the silk sutures *in situ*. Vecchi (6) in 1905 had an almost identical experience with that of Pissemsky. At a second Cæsarean section in the same patient he also removed the tubes which had been securely ligated during the first operation. The ligatures had cut completely through the tubes. The divided ends of the left tube had reunited and the tubal canal had been reestablished. The ends of the right tube were occluded and separated by peri-

toneum. Kossman (7) in 1898 reports a failure after ligation with catgut. Lambach (8), reported by Littig (9) in 1912, ligated both tubes with silk, incidental to an operation for retroversion; term pregnancy occurred three years later. Taylor (10) in 1904 had a rare experience, which demonstrates conclusively the untrustworthiness of tubal ligation. During two successive Cæsarean sections in a rhachitic dwarf, he ligated both tubes; the patient, nevertheless, became pregnant again and was subjected to a third Cæsarean section, at which operation bilateral salpingectomy with cuneiform resection of the uterine cornua was done.

The uncertainty of simple tubal ligation has apparently not been duly appreciated by American gynecologists. Leonard (11) reports two failures from the gynecological clinic of Johns Hopkins Hospital in patients operated upon as late as 1909. These failures occurred in a series of twenty-three patients, in whom sterilization was attempted. He could trace only fourteen of these patients at the time of his report. Five of the fourteen were over forty years of age at the time of operation.

In the two cases of failure the tubes had been doubly ligated with silk. The first patient who was operated upon in 1908 was delivered of a full term child one year later; and the second (operation, 1908) suffered three miscarriages within a period of four years after the operation.

Morris (12), in 1904, in an article, Artificial Sterility, recommended: "Tie a silk thread about each oviduct near the fimbriated extremity; the ligature will become encapsulated and close the oviduct." As late as 1911 Werner (13) asserts that double ligation of the tube and resection of two or three cm. may be relied upon to prevent conception.

Failures after division or resection of the tube between two ligatures. Recognizing that no reliance could be placed upon simple tubal ligation for the production of sterility, Kehrer (14), in 1897, recommended double ligation of the tube near the uterus and section between the ligatures. His first operation was done through an anterior colpotomy. He apparently was not familiar with three cases reported the previous year by Gordon and Sutton, in which removal of the tubes and ligation of the uterine stump had resulted in failure. Priority in advocating double ligation and section is alleged by Kossman in a pamphlet in 1896. Later he proposed division of the tube with the actual cautery between ligatures, and cauterization of the mucous membrane and muscularis if they protrude beyond the serous coat of the divided end. A similar method to that of Kehrer was proposed a year later by Spinelli (15). Two years after the appearance of Kehrer's paper, Abel (16) reported having done double ligation and division of both tubes in 1894 at the time of a second Cæsarean section in a patient. She became pregnant again and was delivered by a third Cæsarean section three years later. Abel found that both tubes in this patient had reunited, but that in only one was the canal patulous throughout. Three other failures are reported by Belser (17). Two of the three women became pregnant in the stump of the ligated and divided tube. A modification of this method suggested by Braun-Fernwald (18) and Rühl (19) consists in burying the proximal portion of the ligated and resected tube beneath the peritoneum of the broad ligament. That this modification cannot be relied upon is pointed out by Reiferscheid (20), who reports a failure after its employment; as follows: At a second Cæsarean section in a woman with a markedly contracted pelvis, two cm. of each tube were resected and the uterine stump buried within the broad ligament. She became pregnant again in one year. After a similar operation done by Smythe (21) the patient became pregnant in seven months. While the technic of subperitoneal concealment of the proximal end of the divided tube proposed by Asch (22) is simpler than some others, it cannot be more efficient. He operates usually through a posterior sagittal colpotomy, sometimes through an anterior colpotomy. Findley (23), following the teaching of Selheim (24), fails to appreciate the uncertainty of ligation and resection of the tube when in a recent article he proposes it as part of a "combined operation for the interruption of pregnancy and sterilization."

Crushing of the tubes, even if followed by ligation in the groove as suggested by Friedmann (25), is no surer than simple ligation or resection. Cassalis (26) reports one failure in ten operations in which both tubes were crushed by a powerful forceps through a colpotomy opening. The patient became pregnant six months after the operation.

Bilateral salpingectomy with ligation of the uterine stumps of the tubes does not appear to render sterility any more certain than do the foregoing methods. Most of the reported failures occurred after operations in which removal of the tubes formed only a part of the operative measures instituted for the relief of pelvic inflammatory disease. Gordon (1896) reports pregnancy occurring in two patients from whom both tubes and ovaries were thought to have been removed and the stumps of the tubes ligated. The first patient menstruated irregularly after the operation and became pregnant three years later. The second patient menstruated regularly, beginning three months after the operation, and became pregnant after fourteen months. At the time of a double ovariotomy, Sutton (1896) ligated both tubes near the uterus and divided the right one with a cautery, the left with a scissors. The patient underwent two subsequent pregnancies, with normal labors, twenty and forty months respectively after the operation. In a case of chronic pelvic inflammation, Schmidt (27) removed the left ovary and both tubes, ligating the stumps with silk. Pregnancy occurred four years later. Polak (28) and Leonard each report the rupture of an interstitial pregnancy occurring in the small remaining portion of a tube after bilateral salpingectomy and ligature of the stumps. Polak's case is of particular interest for the reason that the patient "had been married seventeen years, and had not previously been pregnant owing to a gonorrhea which she had contracted from her husband shortly after marriage." Freeman (29) attended a patient who had a normal labor 400 days after ligature and removal of both tubes, one ovary, and part of the other. During a Cæsarean section Brodhead (30) removed (?) both ovaries because

of multilocular cystic change, and excised the tubes after ligation about one inch from the uterus. The patient menstruated irregularly after the operation and became pregnant within two years.

To these failures after bilateral salpingectomy and ligature of the stump I wish to add two which occurred in my own practice.

Case I. H. K., aged twenty-one years, consulted me in February, 1913. She had been suffering for two months with pain in the right iliac region, intermittent in character and aggravated by exercise. There had been no nausea or other symptoms referable to the stomach or intestines. Bladder symptoms were also absent. Menstruation had been established at twelve years; it was regular (twenty-eight day type) painless, and from two to three days' duration. The last period had occurred two weeks previous to the consultation. She had been married three years, and had been pregnant three times, each pregnancy having been terminated at about the third month by induced abortion. Bimanual examination disclosed an irregular inflammatory mass in each tuboovarian region, larger on the right side. At operation, three days later, both Fallopian tubes and the right ovary and vermiform appendix were removed. The left ovary was adherent to the inflamed tube, but was not so badly diseased as to necessitate removal. The tubes were ligated near the uterus with chromic catgut and the portion distal to the ligatures was excised. The patient made an eventful recovery. She became pregnant thirty months later and suffered no inconvenience as the result of the operation.

Case II. R. F., aged twenty-five years, married, consulted me in July, 1909, suffering from uterine hemorrhage. She had been well until the previous month, when she aborted in the fourth week of gestation. The bleeding which began with the abortion continued in slight amount and was not associated with pain or other discomfort. She had been married four years and had been delivered with forceps two and a half years before. On examination the uterus was found to be retroverted, and its mobility impaired. A mass on either side was diagnosed as consisting of diseased tubes and ovaries.

At operation, August 17, 1909, the uterus was curetted. Through a median suprapubic incision the uterus was liberated from adhesions to the prolapsed and inflamed tubes and ovaries. Both tubes were occluded and both ovaries cystic. The tubes and right ovary were excised, and the uterine stump of the tubes was ligated. The left ovary was resected. The round ligaments were shortened by the method of Montgomery. The patient made an uneventful recovery and, twenty months later, gave birth to a living child.

Bilateral salpingectomy with cuneiform resection of the uterine cornua is considered to be the surest method of producing sterility through operation upon the tubes. It was first proposed by Neumann (31), in 1898, and shortly afterward received favorable commendation from Rose (32). Günther (33) reported five successes after its adoption. All the writers upon the subject agree that in performing the operation great care should be exercised to make the wedge shaped section of the uterine cornu deep enough to remove all of the interstitial portion of the tube and to close the opening in the uterus with two layers of sutures; the deep sutures to approximate accurately the cut surfaces of the uterine muscle, the superficial ones to bring together the cut edges of the peritoneum of the broad ligament over the repaired muscle. Notwithstanding the observance of all such precautions, failures are reported by Küstner (34), Polak, and Häberlin (35). Küstner observed failures in two patients in whom during the performance of vaginal fixation of the uterus he removed a wedge shaped section of both uterine cornua and about three cm. of each tube. Severe hemorrhage occurred in both cases during the operation and pregnancy followed a few years later. Because of the hemorrhage, the difficulties to be overcome, and the uncertainty of success when the operation is done through vaginal section, Küstner advocates the abdominal route. The most conclusive evidence of the value as well as the possibility of the failure of cornual resection is to be found in the experience of Häberlin. He resected the tubes and uterine cornua in forty-one patients for the purpose of rendering them sterile, and was successful in forty of them. In some of the patients the operation was done through a colpotomy, and the others through abdominal section. He expresses a preference for the latter method.

In Group II of this classification are recorded several cases in which a subsequent operation in the same patient revealed the failure of the previous operation to produce a permanent occlusion of the tubal canal. While no pregnancy had occurred in any of them, there was found an unobstructed passage between the uterine and peritoneal cavities, and pregnancy might have occurred. Rühl performed bilateral salpingo-oophorectomy, ligating the uterine stumps of the tubes with silk. Two years later he reopened the abdomen and found one tube patulous. As a result of this experience, he suggested that the ligated tubal stump be buried beneath the peritoneum of the broad ligament. Ries (36) reports three similar cases which came under his observation. In the first patient bilateral salpingo-oophorectomy with ligature of the stump was done. At a subsequent abdominal section he found one tube open. The second patient had both tubes and the right ovary removed, and at second operation presented a uteroperitoneal fistula at each cornu. Vaginal hysterectomy, performed in the third patient some months after a bilateral salpingectomy, demonstrated an unobstructed canal in the remaining stump of each tube. Similar experiences are reported by Bovee (37) and Fränkel (38).

Group III of this classification includes methods some of which are modifications of the foregoing and some others which present elements of novelty. While apparently satisfactory results have followed their application, the number of cases in which each method was used is not sufficient to stamp it with unqualified approval. In commenting upon Kehrer's paper, Beuttner (39) proposed resection of a portion of the muscularis and mucous coat of the tube after an incision through its serous coat. The cut ends of the muscularis are then to be occluded by suture, covered with serous membrane, and attached to each other. He recommended abdominal instead of vaginal incision. The method of Kirschoff (40) is similar. It consists in subserous resection of three or four cm. of the tube through a small incision in its peritoneal covering parallel to its long axis. He asserts that sutures are not necessary, as adhesion of the inner surfaces of the tubal peritoneum produces a fibrous cord which occludes and permanently separates the divided ends. Van Meter (41) makes the same resection, but sutures the muscularis first to occlude the lumen of the tube. When Cæsarean section is performed through a transverse incision in the fundus, the method of

sterilization used by Halban (42) should be as effective as cornual resection. He excises the interstitial portion and three cm. of the tubes by extending the incision well into each cornu. In closing he first introduces a musculomuscular suture and covers the repaired muscle by suturing the peritoneum over it. Taussig (43) also combines cornual resection with removal of about two cm. of the uterine end of the tube, but goes further. After closing the opening in the cornu, he ligates the proximal end of the remaining portion of the tube and buries it deeply within the broad ligament. He then draws a loop of round ligament over the repaired cornu and attaches it to the upper posterior surface of the uterine fundus. His method does not appear to offer the degree of surety of salpingectomy and careful cornual resection.

Rissmann (44) proposed wedge shaped resection of the cornua, but to leave the rest of the tube undisturbed so that the tube might be repaired and its canal restored if the patient subsequently desired to become pregnant. With the same purpose in view Selheim buries the entire tube beneath the peritoneum of the broad ligament so that if desired it may later be restored to its former peritoneal position without injury to itself. It is difficult to imagine the tube remaining within the broad ligament for any length of time, without undergoing changes which would render it unserviceable for further transmission of spermatozoa. To accomplish temporary sterilization Holzapfel (45) divides the tube at the junction of the middle and outer third; resects about two cm. of the uterine portion after carefully dissecting off its peritoneal coat. The end is then ligated with fine catgut, covered with the dissected peritoneum, and buried within the broad ligament. The cut end of the outer portion is ligated and allowed to remain within the peritoneal cavity. This operation presents the same uncertainty as do all others in which the uterine cornu is not resected and sutured. If restoration of the tubouterine canal at a later date is to be considered in the production of sterilization the operation of De Tarnowsky (46) appears to be the most satisfactory. The steps are as follows: "Amputate the tubes on either side one fourth inch from the uterine cornua. With a fine rat toothed forceps or a probe invaginate the distal half of each stump and close the lumen with two catgut sutures. This produces a seroserous adhesion which will effectively close the canals. On the posterior uterine wall make two parallel vertical incisions one inch long and one half inch apart. These incisions should not be over one fourth or one fifth inch deep. With a curved forceps burrow between these incisions, creating a canal of sufficient size to contain the two tubes. With the same curved forceps remaining in the new canal, grasp the opposite tube and draw it through the canal so that it emerges on the opposite side. Reintroduce the forceps from the opposite side and repeat the same procedure with the remaining tube. In the new canal the tubes should be parallel to each other, one lying above the other, the cut extremity of each tube emerging on the opposite side of the new canal. Make a small cuff by everting the tubal mucosa (it is sometimes necessary to make two small incisions before being able to evert satisfactorily) and secure the cuffs to the margins of the new canal by fine catgut stitches which may be present. Test the patency of both tuber by means of a fine probe." Rockey's (47) operation differs from this, in that he does not draw the ends of the tubes through incisions in the posterior wall of the uterus, but simply attaches them to the surface of the uterus with sutures. The operation of Menge and Kroenig as described by Blietz (48) presents some points of difference from the others. In correcting retroversion and prolapse of the uterus by the Alexander-Adams operation, they opened into the peritoneal cavity by two inguinal incisions, removed the outer half of each tube, and attached the remaining portion to the aponeurosis of the external oblique. Unaware of this report, Stettin (49) proposed practically the same procedure.

In Group IV the results of experiments carried out upon animals with the object of determining the most positive method of tubal sterilization, with but few exceptions, corroborated the clinical experience in the human being. The early workers in this field were Kossman, Landau (50), Woskressensky (51), Josephon (52), and Ratschinsky (53). The more recent contributions to the subject are those of Fränkel, Ronsse (54), Friedmann, and McIlroy (55). Kossman's experiments, performed in 1875, consisted in ligating the Fallopian tubes of young pullets with heavy silk ligatures. In six weeks they began to lay. Examination of the tubes at autopsy revealed that the ligatures had broken as the result of swelling of the tissues and had become incrusted with lime salts. Fränkel experimented upon twenty-six rabbits, on which he performed thirty-three operations upon the tubes and twenty-nine upon the uterine cornu in his attempts to obliterate the tubal canal. Only two successes followed the thirty-three operations upon the tubes, while the operations upon the cornu all resulted in failure. The character of the failures following the several methods is interesting. 1. After single or double ligation with silk, catgut, or rubber, he found that the tube had been cut through by the ligature and the ends had either reunited or had reopened and formed a tuboabdominal fistula. 2. After section of the tube with or without ligation the canal in each end was found to be patulous or the ends had reunited and the continuity of the canal had been restored. 3. Resection of one to 2.5 cm. of the tube between ligatures was frequently followed by tuboabdominal fistula. 4. Cauterization of the interstitial portion of the tube resulted in failure in every instance. He concluded that the only certain method of tubal sterilization consists in total extirpation of the tube, including the interstitial portion in the uterine cornu, and careful closure of the cornual defect. The results in Friedmann's experiments in twenty-two animals corroborate those of Fränkel. He operated upon rabbits, cats, and bitches, chiefly by crushing the tubes and ligating in the furrow with catgut or silk sutures. Seventeen of the animals became pregnant after the operation. Autopsies performed six weeks after the operation in the five remaining animals (rabbits) disclosed patulous tubal canals in four of them, and complete obliteration in only one. Rousse's conclusions dif-

fer from those of Kossman, Fränkel, and Friedmann. He experimented upon the tubes and uterine cornua of rabbits by performing simple ligation; simple division; division or resection between ligatures. All the animals were subjected to autopsy shortly after the operation. He found complete occlusion of the tube in all. In addition to the occlusion in cases in which operation upon the cornua had been done, there developed a cyst lateral to the point of ligation or division. Those whose tubes were doubly ligated presented a hydrosalpinx between the ligatures. Because of the occlusion and the cyst formation, he concludes that the passage of ova and spermatozoa would have been permanently prevented. He believed that the fluid which accumulated in the tube was a normal secretion, rather than the result of inflammation or disturbed circulation. Since the animals were all killed, however, before the swelling incident to the trauma could possibly have subsided, his results cannot be considered as convincing.

From this résumé of the clinical and experimental experience with tubal sterilization, I believe that we may fairly arrive at the following conclusions:

1. There is no method of tubal sterilization which affords absolute security against conception.

2. Simple ligation of the Fallopian tubes with either single or double ligatures has been followed by the largest number of reported failures.

3. Excision of a wedge shaped section from each cornu of the uterus, followed by careful closure of the opening with musculomuscular and seroserous sutures has yielded better results than any other method.

4. In the light of our present knowledge it seems unwise to advocate any other method than cornual resection. These conclusions are in accord with those arrived at in previous reviews of this subject by Charles (56), Geissler (57), Günther (58), Mironow (59), Offergeld (60), Perdrizet (61), Pestalozza (62), and Sarwey (63).

MILITARY PREPAREDNESS AND THE SURGEON.

An Experience as Post Surgeon at Camp Tanner During the Spanish-American War.

BY GEORGE N. KREIDER, A. M., M. D., F. A. C. S.,
Springfield, Ill.

First Lieutenant, Medical Reserve Corps U. S. Army.

The duty of the medical profession in the event of either peace or war is to conserve life and minimize suffering. In war this duty is especially difficult and dangerous—all the more reason why we should acquit ourselves with credit.

It cannot be denied that wars in America have found the country with an army and the medical profession unprepared to give the best possible medical and surgical attention. In the Revolutionary war the army was a shifting and undisciplined mass of men, without uniforms and improperly shod, poorly paid and fed; it is a wonder that anything was accomplished. However, the individual soldiers were born, gun in hand, and knew the Indian methods of warfare. They muddled through seven years of skirmishing, and by good fortune

won. The medical profession does not seem to have drawn any particular renown or credit from its services in this war.

It was not long after the close of the Revoluion that the forces of St. Clair, undisciplined and inexperienced, were almost annihilated by the savage Indians of northwestern Ohio. The second expedition, properly organized and drilled under Wayne, was more fortunate. We know little of the action of the doctors in these terrible events. I believe they have left no records.

The war of 1812 was short, and except for the battle of New Orleans was not creditable to America. We know little of the services of the medical men; then, as before, no records were kept and perhaps it is well that none were kept. There was not a single medical journal published in America at that time.

The Mexican war of 1846 did not call out many men, but there was a mortality from the preventable diseases, yellow fever, typhoid fever, and dysentery, amounting to over 16,000.

The Civil War tested the strength of both sides to the utmost. The northern medical forces had much the advantage of the southern in supplies of medicines and surgical instruments. There was frightful incapacity of the medical staff of both armies for a number of months. Surgeon General Hammond's letter to the Secretary of War, in 1862, revealed the unspeakable suffering and death of many men due to inefficient ambulance service after battles. This was not the fault of the medical staff.

Old soldiers have told me their particular dread was that they might fall into the hands of the doctors or be sent to the hospital. The mortality from preventable diseases in all quarters amounted to over 300,000. Finally the army and medical corps were beaten into shape. Hospitals of proper construction were erected. Statistics were kept and there was some glory for our profession. The *Medical and Surgical History of the War of the Rebellion* was for those days a monumental work.

The Spanish war found us again full of the enthusiasm to do or die for the dear old U. S. A., but we had virtually no medical or surgical preparation. The mortality from preventable diseases was more than ten times that from the bullet.

I was on duty as post surgeon with the Illinois troops when rendezvoused at Springfield. About 10,000 came together and were placed in the State fair buildings and grounds, beginning on April 28th. For three weeks the weather was cold and rainy. The men slept on cold cement floors. The buildings were large and draughty, the toilet facilities were inadequate. There were no bathing facilities. The cavalry regiment camped in the open race track enclosure. The tents were often surrounded by water, but this regiment had a regular army officer for its commander and came out of the camp in good physical condition. The seriously sick and injured were taken to St. John's Hospital, which was filled to its capacity at that time. I have the records of all that were then treated, seventy-eight in number. Among these there were six cases of meningitis with three deaths, thirty-two cases of pneumonia with four deaths, and three deaths from all other causes. There were only two cases of typhoid fever with no death. After four or five weeks in Camp Tanner, the troops were mustered into the regular service and left for the national camps. It seems that at least some preparation for good water and for medical and surgical supplies for the small army might have been provided by the war department in five or six weeks' time, but I am quite sure that such provision was not made. I make no charges, but am simply trying to state facts.

The newspapers gave such an account of the general confusion at Washington that I felt quite sure there would not be provision made for medical and surgical supplies for the Illinois toops. I therefore laid the matter before Adjutant General Reece and Governor Tanner. I suggested that we furnish each regiment with a thirty day supply of medicines and surgical dressings and a minor operating case. They authorized me to do this. Each regiment left Springfield with two large packing cases of supplies. Nearly all the regimental surgeons later thanked me for this service. I remember particularly that Major Sullivan of the Seventh regiment wrote me that when they reached Camp Alger within sight of Washington, D. C., they found that none of the other regiments there was supplied with medicine. The word went out that the Seventh Illinois had supplies. The post commander made a requisition on the Seventh to turn over its supplies, and the medical officers of the Seventh preserved their supplies only by burying them. A number of the Illinois troops, notably the First Cavalry, went to Chattanooga, where ten per cent. of the strength were taken sick with typhoid and several died. The same held true of the camp at Jacksonville, Fla., where there were 1,500 cases of typhoid in the corps of 30,000. The sickness in the regiments of the regular army encamped alongside the volunteers was remarkably less than that of the latter.

The scandal of the unpreparedness of all departments of fighting forces of the United States on land is mentioned with shamed faces to this day. The navy was better prepared and made a proud record. Fortunately our contest was with a weak and decadent nation. If it had been against a strong and vigilant nation, our record might have been different. Before leaving the subject of Camp Tanner I might say that soon after the rendezvous began the surgeon general, Senn, took charge of the medical department. He secured a subject and each night gave a lecture describing the various surgical operations such as amputations, resections, and ligations, performing them on the cadaver. However valuable these eloquent and instructive lectures were, I am free to say that they were not what was needed for the fifty surgeons just beginning service in a war in the field. I am quite sure that had lectures been given at Camp Tanner on the methods of water sterilization and personal hygiene of troops, much saving of life might have resulted. The fact is that probably not one hundred surgical operations were performed on the 12,000 Illinois troops during the whole war, while on the other hand there were probably not less than 2,000 cases of preventable illness and a number of deaths.

To emphasize this preliminary statement I insert

here the advertisement of the Harvard Medical School, offering to give this summer a course in military medicine:

One result of the European war has been the realization by intelligent citizens that this country is very inadequately prepared to meet a foreign invasion, and a conviction on the part of many that a foreign war is at least a possibility which we should be prepared to meet. We know, from our own experience in the Civil War and in the Spanish-American war, as well as from information about the present war in Europe, that physicians in civil life are not capable of becoming efficient army officers without additional training. Any adequate plan of military preparedness necessarily involves provision for the proper medical care of our soldiers. The medical profession must be prepared to meet the demand for efficient medical officers or face the disgraceful fact that its imperfect knowledge of camp sanitation and of the administrative duties of a medical officer is responsible for greater loss of life among our soldiers than are the bullets of any enemy. Such was the story in the Spanish-American war, where the chief losses were in regiments in camp, which never left this country. We must not allow this national humiliation—this disgrace to the medical profession—to be repeated.

The Harvard Medical School may well feel proud of what it has already done for the cause of humanity in connection with the European war. It has organized and sent abroad three complete hospital units, whose combined terms of service amount to twelve months; and Professor Strong and other instructors took a prominent part in the successful campaign against typhus fever in Serbia. We are not satisfied, however, to rest upon these laurels, but are determined to do all in our power to aid the cause of preparedness in this country.

Few appreciate the magnitude of this problem of applying proper medical care for a large army. It is not improbable that in case of war we should need to put in the field an army of a million men; the experience of the present war forbids us to think seriously of smaller numbers. For such an army there should be ready from twelve to fifteen thousand well trained medical officers. This would mean approximately one in ten of the registered physicians of the United States.

We have at present in the regular army, including contract surgeons, only 550 medical officers. If we add the medical officers of the militia and the relatively small number of those in the medical reserve corps who are now prepared for actual field service, the number of properly prepared physicians now available is not over twelve to fifteen hundred—or approximately one tenth of the number that would be needed for any serious foreign war. It is a mistake to think that efficient medical officers, any more than efficient soldiers, can be had without training, for the efficiency of the army depends on preserving its health. When nine tenths of the medical officers, in case of war, must come from civilian physicians who are at present untrained for such work, is it not the duty of every patriotic physician to prepare himself for such possible service, if he can do so? Is it not the duty of our medical schools to afford opportunities for such training, as far as they can?

We must not forget to record the great medical triumph of our army medical corps, which came as a result of the occupation of Cuba, viz., the discovery of the sources of yellow fever made by Surgeon Walter Reed, in 1900, and the consequent possible eradication of this disease from the tropics. It is believed that this discovery alone has been worth in life and treasure all the expenditure and suffering endured in the war of 1898. We must also render homage to our medical corps, which holds the front rank in making possible the Panama Canal. Never in the history of the world has the medical military officer stood as high as he stands today.

We not infrequently hear it said that, in case of war, civil surgeons could quickly assume the duties of army surgeons, and, aided perhaps by railroad and executive officers and the comparatively few medical officers of the regular army, could meet the problems of caring for the wounded successfully. So far as the actual surgical treatment of wounds is concerned this is true. But, as the late Doctor Rodman, president of the American Medical Association, recently said in his testimony before the committee of Congress: "I went into the army as a contract surgeon in 1880 and served seventeen months. The strictly professional part of my work was the easiest part of what I had to do." Without doubt, hospital units for base hospitals, composed of carefully selected civil surgeons, would be of great value. A glance at the list of duties of the army medical corps, however, will show the need for special training. As given in the surgeon general's report to the chairman of the committee of military affairs, House of Representatives, these are:

a. Professional care of the sick and wounded in garrison, on the march, in camp, on the battlefield, and after removal therefrom.

b. Investigating the sanitary conditions of the army and making recommendations in reference thereto, including the location of permanent camps and posts, the adoption of systems of water supply and purifications, and the disposal of wastes.

c. Making physical examinations of officers and enlisted men.

d. The management and control of military hospitals.

e. The recruitment, instruction, and control of the hospital corps and the army nurse corps.

f. Furnishing all medical and hospital supplies.

g. The direction and execution of all measures of public health among the inhabitants of occupied territory.

h. The methodical disposition of the sick and wounded, so as to insure the retention of those effective and to relieve the fighting force of the noneffective.

i. The transportation of the sick and wounded.

j. The establishment of aid stations, dressing stations, hospitals, and other formations for the care of the sick and wounded.

k. The preparation and preservation of individual records of sickness and injury in order that claims may be adjudicated with justice to the government and to the individual.

l. The instruction of the troops in personal hygiene.

m. In addition to these duties, specifically prescribed, medical officers are required to act as members of retiring boards, examining boards, and courts martial, and as instructors for the organized militia.

In view of these facts I suggest the following statements: The Illinois State Medical Society at its annual session of 1916 believed that:

1. The members of this organization are anxious and willing to prepare themselves for proper professional service during any crisis which may arise, and which may necessitate our fellow citizens taking up arms.

2. The duties of the medical profession in the event of war become so important and onerous that not less than seven surgeons should be provided for every 1,000 troops.

3. Schools and camps for the instruction of medical men in the duties peculiar to army service should be provided in the near future, and all registered medical men between the ages of twenty-three and forty-five years who can prove themselves physically and mentally fit for service, should be eligible to receive this instruction.

4. The death rate of the medical corps in modern wars has become so great that to prevent a deficiency of trained men, no medical man should be allowed to serve in the ranks. (The losses of medical officers in the German army up to November, 1915, were 1,491; of the Austrian army, 1,722.)

5. The preparedness and skill of the German medical corps has been of remarkable value to the army of that nation. Undoubtedly the other leading nations have gradually been able to become nearly as efficient. But the lesson of German preparedness of the medical corps should not be forgotten in preparing ourselves. With all the

preparations made, the German medical army was found lacking in the early days of the war. Professor Czerny has stated that numerous trains loaded with wounded came into Heidelberg unprovided with either surgeons or nurses.

6. Should it be necessary to call out the estimated full war strength of the nation, namely 20,000,000 soldiers, a minimum of 140,000 surgeons would be required. There would then only be about 25,000 remaining to render medical and surgical aid to approximately 80,000,000 people. The possibility of these conditions should be considered and suitable provision be made to meet them.

7. The American light automobile ambulance has been shown to be so valuable in the European war that this form of conveyance in ample numbers should be provided for our forces with the least possible delay. On the 1st day of May, 1916, as I understand it, not a single auto ambulance was listed in the equipment of our army.

8. The x ray and giant magnet have become so essential in the treatment of wounds made by modern weapons that the army should be amply provided with these instruments of precision. It would be interesting to know whether the army is supplied with these instruments in portable form.

9. The modern chemical and biological laboratories have been shown to be essential to care and maintenance of any army by—

a. Providing serum for prevention or inoculation against or for the cure of typhus, typhoid, tetanus, smallpox, cholera, dysentery, diphtheria, erysipelas, gonorrhea, and syphilis.

b. For securing safe water supplies.

c. For the destruction of infecting insects, rodents or parasites, such as mosquitoes, lice, flies, rats, etc.

10. Our experience in civil practice, as well as the remarkable revelations of the great war abroad, have shown that alcohol in every form should be rigidly excluded from the camps of the recruit and the seasoned veteran.

11. Notwithstanding the strenuous efforts made to prevent venereal diseases in the foreign armies, we learn that there has been very great difficulty in combating diseases of this character during the present war. We therefore suggest that the methods of preventing such diseases in the United States army that were in use up to a recent period be again provided. It is wrong to ignore this danger.

12. In trench warfare the use of barbed wire, suffocating gases and hand grenades, as well as other means of destruction, have introduced new factors into the science of war. The medical supplies should be on hand and the medical profession taught how to treat these new methods of injuring soldiers.

13. Provision should be made to continue life and accident insurance of the profession while on war duty. This will probably necessitate increase in the rates of insurance at such a time.

14. Experience has proved that volunteer surgeons, i. e., those not connected with the regular service or the Red Cross service, and having no responsible standing, are not likely to render efficient service in time of war. The same principle applies to volunteer nurses, these being usually society women who desire to shine in the limelight for a brief period. Regular, continuous, systematic, intelligent service on the part of surgeons, nurses, and hospital employees is what counts in the time of stress.

15. One of the greatest services of medical men is the accurate statement of facts; example, each side early in the present war accused the other of using dum dum bullets. This was probably not true of either side. Each side has accused the other of burning out the eyes of children, cutting off the hands of old people. This has been shown to be probably not true of either side. The facts of war are always distressing enough. They should not be magnified by enormous untruths.

16. Finally and above all, the medical profession should exercise its highest powers of mental and moral restraint and insist that humane methods and thoughts be uppermost, even in the face of carnage. Ordinary humanity has failed, religion has failed, all other known means of civilization have failed to prevent wars. The motto of the medical profession is: *Do no harm*. Let us hope that with this motto the brotherhood of medical men all over the world may rise to a great opportunity and find a basis on which all may unite to bring peace and good will between all men now and forevermore.

RUBELLA OR GERMAN MEASLES.

A Study,

By Edward Gray, M. D.,
Berkeley, Cal.

Cases of rubella present themselves before the family practitioner in but small number, in general, and usually of only the mildest type; it has been my fortune to see 283 cases since June, 1908, of all types, and it will be the object of this paper to summarize the experience gained thereby and to present some practical deductions relating to causation, diagnosis, prognosis, and treatment.

It is a misfortune that this disease is known under so many different names; for example, roseola, French measles, German measles, false or bastard measles, hybrid scarlatina, Rötheln; and a number of others. While the International List of Causes of Death recognizes the term German measles, it is clear to me that rubella is the best title: for this malady is neither measles nor scarlet fever, nor a hybrid of the two, but an independent, contagious, eruptive fever, specific and epidemic; and characteristic in its history of incubation, invasion, eruption, and clinical course. It affects children chiefly, but not exclusively. I have a list of forty adults between twenty and fifty years of age, whom I saw mostly during 1911. The history of these adults will be shown to be important in the variety of symptoms.

Rubella is doubtless a germ disease as shown by its period of incubation, invasion, exacerbation, and decline, although the exact germ or living principle has not yet been discovered. It occurs in epidemics affecting mainly the families of the better classes and the inmates of institutions, particularly of orphan asylums. The contagion resides probably in the oral and nasal secretions and certainly in the desquamated epithelium. The period of contagiousness extends probably from the first outbreak of the rash until desquamation is nearly completed. Neither measles nor scarlatina protects against rubella nor does it protect against them. It is less protective against itself than has been supposed; for of the sixty-three or sixty-four cases occurring in 1908 one third, or twenty-one cases, had relapsed in 1911. Five of these twenty-one were in adults, twenty years old or over. The writer in the *Reference Handbook of the Medical Sciences*, VI, who records that "there are no clearly proved instances of its recurrence in the same individual," would doubtless wish to withdraw that statement now, twenty-one recurrences having fallen under the eye of a single observer. A case of relapse also occurred in 1908; all these were in children. No case of reincidence or relapse was severe or fatal. This favorable issue is the more interesting because one patient, a boy ten years old, is the only one in whom a sequela—namely, acute nephritis—developed. This was in 1908 and was the sole instance of the kind in the whole series of 283 cases.

ETIOLOGY.

Age. Rubella is a disease *sui generis* commonly affecting children, and these chiefly between the ages of three and fifteen years. These children belong

mainly to the families of the better classes, or else are inmates of institutions or homes, orphan asylums in particular. Adults do not always escape; it has been my lot to see thirty-six adults affected (among 158 cases), distributed thus: Twenty-four cases between twenty and thirty years; six cases between thirty and forty; six cases between forty and fifty; thirteen of these were in men and twenty-three in women. It is propagated by itself and by no other malady. This point needs some emphasis in view of an article in the *Lancet* so recently as June 29, 1911, wherein the writer sets forth the notion that rubella is a variety of measles. The distinction may best be shown in the paragraphs given to diagnosis.

SYMPTOMS.

The chief symptoms of rubella are: A stage of incubation; a stage of invasion (though this is frequently absent); a characteristic maculopapular rash or exanthem; swelling and induration of various lymphatic glands, particularly the postcervical and inguinal; swelling of the tonsils and sometimes pharyngitis; fever, usually of mild type; and desquamation of cuticle.

The period of incubation is usually twelve or fourteen days, but may vary between eight and twenty. Twelve was the average here in 1908 and 1912; and fourteen (infrequently fifteen or sixteen) in 1911. Never is the stage of incubation so brief as in scarlet fever. In mild cases the stage of invasion is often skipped, but it is usually seen in the severer cases. While it may last from three to fifteen hours, it is ordinarily brief. The usual history is that the child has gone to bed apparently well and has waked in the morning with the rash. Headache, rigors, convulsions, and vomiting are exceptional; but headache and backache are common enough in adults and were so marked in four of our recent cases as to recall variola. At the close of this stage and concurrently with the rash, occurs the important symptom of enlargement of the postauricular, postcervical, and other lymphatic glands. The chief visible symptom, namely, the rash, now appears. It begins on the neck and along the lower jaw from the nostrils and mouth to behind the ears and spreads rapidly downward over the whole body. In rare cases it appears first on the back or chest. It may, exceptionally, halt with distinct intervals, so that there are two or three crops; this occurred in 1911 in the person of the first grown woman affected here, an employee. It is possible for the rash to fade on the chest and face before invading the limbs, but the usual course is steady, and it reaches the feet in from twelve to twenty-four hours. The exanthem consists of very minute macules or maculopapules of a pink or pale rose color with areas of untinged skin between, seldom confluent. The more discrete the eruption, the more it looks like measles; the more confluent it is, the more it resembles scarlet fever; but the color has never, in my estimation, the vividness belonging to scarlatina. Its hue is best seen upon the back and the inner surface of the thighs. It is hardly elevated above the surface. It presents two types; one strongly resembling measles, which has been named rubella morbilliformis; and the other, like scarlatina, rubella scarlatiniformis. Doubtless the idea of a hybrid disease arose from this circumstance. "The eruption may reach its height in one part before appearing in another; this is a point of value in diagnosis and of contrast to scarlatina and measles." Over any particular area the rash may begin to fade in a few hours, and this fading is seldom delayed beyond twelve hours. It has been noted to disappear one day and then return. Before fading the rash may be greatly altered by the spreading of a bright red flush over the face and neck, and of a fine punctate rash like that of scarlet fever on the limbs at the same time. General erythematous redness of the skin has been noticed. The duration of the eruption is from one and a half to three days, two and a half or three being the usual course. The rash is seldom accompanied by itching, which, if present, is but mild and mentioned only on questioning. A faint brownish yellow pigmentation may sometimes be observed after the eruption has subsided. It seems to have no relation to the severity of the rash. During the stage of eruption a mild fever is usually present, between 99.5° and 101° F.; sometimes, however, in the more severe cases it runs to 102° or even 103°. A temperature exceeding 101° should cause a search for complications. In three cases presenting the complication of acute endocarditis I have seen a temperature of 106°, 109.2°, and 109.6° F. respectively. Manifestly the hyperpyrexia was due to the malignant endocarditis, not to the rubella. The rate of the pulse and of the respiration accords with the degree of fever.

The second cardinal symptom of rubella is the swelling of the postauricular, postcervical, suboccipital, and inguinal glands. This sign may be called well nigh pathognomonic. The enlargement of the glands about the neck always occurs early and, according to Dawson Williams, may be detected as long as a week before the rash appears. I have not sufficient data upon this point just now to either confirm or confute. The enlargement of the inguinal glands was particularly noticed in the epidemic of 1911, existing in at least two thirds of the cases and in every adult. The inguinal glands do not swell so early as the cervical; usually not until the rash begins to decline; while swelling of the postcervical ones probably never fails to take place. This adenopathy is important in differential diagnosis. Some patients, a few only, had, in the summer of 1911, swollen lymphatic glands below the axilla, not in it.

Infrequently the eruption will affect some of the mucous membranes; we may therefore have a pharyngitis or an amygdalitis; a conjunctivitis; a bronchitis, or even some diarrhea. This was the type of the third epidemic seen here (1912), which strongly resembled morbilli in course and complications and led to three deaths by bronchopneumonia. Out of 158 cases in 1911 there were three mild sore throats: two of catarrhal conjunctivitis; two of bronchitis; two of amygdalitis in 1908, but no pneumonia in either 1908 or 1911. Bronchopenumonia appeared in 1912. All these affections of the mucous membranes were mild and soon subsided in 1908 and 1911; they were severe in 1912. In crowded populations, however, bronchitis and pneumonia may prove formidable; or when the morbilliform type prevails as in our epidemic of 1912.

Headache, rigors, convulsions, and vomiting are all exceptional. Headache and backache often occur among adults, and were so marked in four such cases in 1911 as to suggest variola.

The final symptom is desquamation. This is characteristically fine, branlike, or furfuraceous; often scanty in amount, but sometimes moderately copious and in small flakes. The quantity is sometimes so small that the medical attendant or the family is led to believe that there is none; on the other hand, it is occasionally copious enough to allow of shaking out a measurable quantity from the sheets every morning. When it is scanty, we must search under the clavicles. My recent experience leads me to believe that the family physician usually sees but a portion of the desquamation; that in private practice the patients are allowed to dress early and much of the phenomenon of desquamation escapes observation. The duration of desquamation is from one to three weeks; it is prolonged in the ratio of the thickness of the patient's cuticle. I have seen a single case where it lasted for more than a month owing to the thickness of cuticle upon the sole of the patient's foot. Our experience here negatives Edwards's assertion that the average duration is perhaps three days; ten or twelve is nearer the fact. In case of doubt put the patient into a bath: as the water begins to dry off the skin, the shedding of cuticle shows most plainly. The period of desquamation has a practical relation to prophylaxis, as must be apparent.

COMPLICATIONS.

Complications are not frequent in rubella. When present, pharyngitis, tonsillitis, and bronchitis are the most common; then gastrointestinal catarrh and conjunctivitis; while maladies of the serous membranes must be rare. Nevertheless, pleurisy does sometimes occur, and three cases of malignant endocarditis have fallen under my own observation; while Edwards has met one case of tuberculous meningitis. Bronchopneumonia and pleuropneumonia occur as complications and were the cause of three deaths in the third epidemic; they are probable in centres of population. The only sequel which I have encountered thus far is a single case of desquamative nephritis in a boy five years old. While it was a very marked case, the patient recovered in ten days.

DIAGNOSIS.

A typical case of German measles should present little difficulty in recognition. The diagnosis is made by inspection of the skin and of the faucial mucous membrane, and by palpation of the lymphatic glands behind the ears and in the neck; and—later, usually—in the groin; and in the more doubtful cases by the history of the invasion. The diagnosis usually lies between this disease and measles or scarlet fever; but occasionally glandular fever and the nonfebrile skin affections erythema and dermatitis have to be reckoned with. The distinction from measles is usually ready. While the rash of rubella often strikingly resembles that of measles, it is paler in color and presents no characteristic crescentic grouping. More important is the difference in the prodromata; the presence of Koplik's spots in measles and their absence in rubella; the abrupt onset of rubella, often without catarrhal symptoms, and the three days of the latter in measles preceding the outbreak of the rash. Measles, moreover, has not the swollen glands characteristic of rubella; while the conjunctivitis and the fever in measles are of far higher grade and last longer than in rubella. Bronchitis and bronchopneumonia are frequent complications in measles, seldom seen in rubella. Rubella is also devoid of the peculiar mouse nest odor often noticeable in measles. If the existence of measles without eruption is admitted, then the distinction would be difficult indeed and must depend entirely upon the position of the lymphatic glands affected plus the history of the invasion. Typical cases of scarlet fever and rubella are readily distinguished; for the former is a more intense disease in every way; in the nausea and vomiting and—in young children—the convulsions of the prodromal stage; in the pronounced sore throat and the strawberry tongue; in the vivid color of the rash and its broad extent, leaving no sound skin visible in the affected area; in the burning and itching; in the longer duration of the eruption and the much higher degree of the fever; in the frequency and severity of the complications; and in the lamellar character of the desquamation and the large size of the flakes. It will sometimes be impossible to discriminate, by the eye alone, between aberrant cases of rubella and scarlatina, particularly in some of the very mild cases of the latter. It is just here that the position of the swollen glands becomes of so much importance. Involvement of the tonsils is an integral part of scarlet fever; and likewise, usually, of the anterior cervical glands. Hence, if the swollen glands lie at the angle of the jaw or under the tongue, the malady is scarlet fever and we should be on our guard against a postscarlatinal nephritis, particularly in these mild cases; if, however, the glands involved are posterior to the sternomastoid muscle, or border the axilla, or lie in the groin, then the disease is rubella. The time of incubation is also a factor in diagnosis, the period for rubella averaging two and a half to three or four times as long as that for scarlet fever; and being longer than that of measles by two to six days.

Given a case presenting a fleeting rash and a fever of 102° F. or more, the rash not seen by the physician, then the diagnosis between rubella and glandular fever might be impracticable for a day or two until the staining of the skin and a desquamation should declare for rubella or their absence for glandular fever. The latter, moreover, has an incubation period of about seven days, one half that of rubella.

I have seen cases of rubella devoid of apparent fever, which required discrimination from lichen, dermatitis venenata, or other nonfebrile skin diseases. A little attention decides; for the skin disease is not accompanied by chains of enlarged glands nor preceded by a definite period of incubation; and the poison oak eruption itches intensely.

While a "fourth disease" has been described it has not obtained sufficient recognition to demand notice here. Edwards's table of differential diagnosis is to be commended.

PROGNOSIS.

In private practice there are few diseases so free from danger as rubella; but in hospitals and institutions, particularly in large cities, and when the surroundings are unhygienic, or in cases in which the child has been delicate previously, it is more serious. The mortality may then run between one and nine per cent. Edwards, in Philadelphia, records 4.25 per cent. I have myself seen six fatal cases in 284, or a trifle over two per cent. (2.1). Complications and sequelæ are comparatively seldom seen, "and when present are usually of the mildest character" (Holt). When the complication is either endocarditis, pneumonia, or diphtheria, it may well prove fatal. Endocarditis was the cause of the first fatalities which I have seen and was confirmed in each instance by post mortem examination; bronchopneumonia, of the second group of three fatalities.

The type of various epidemics varies in phenomena and severity. No one of the three epidemics observed by me resembled any other.

TREATMENT.

There is no known specific for rubella; but it is not well to leave the patient without treatment; for it has been shown that serious and alarming complications may arise, and there is a recorded mortality of 4.25 per cent. in one epidemic and nine per cent. in another. Some thoughtful care may therefore well be given to treatment. The patient should be put to bed, in isolation, and kept there until the rash has disappeared, say four or five days. Much objection will often be made to going to bed, but the objection should be overruled. All unnecessary visiting is to be prohibited, and isolation should be maintained for seventeen to twenty-one days, or until desquamation is completed. The diet should be light and fitted to the requirements of each case. The young patient is to be allowed to drink freely milk well diluted with lime water, barley water, or lithia water; or whey or weak lemonade, or orange water flavored with glycerin. A cup of hot milk and water flavored with a little tea or perhaps cocoa will be of advantage at times in bringing out the eruption.

The one drug which may be commended for its service is calcium sulphide; but it must be in efficient preparation, well protected from the atmosphere. The doses will be according to the patient's condition rather than the age, and will vary from one sixth grain to two grains or more; and the interval from three hours down to a half hour. The object is to render the blood an unwholesome field for the growth of the specific virus. For restlessness and fever, sweet spirit of nitre, in sweetened water, alone or combined sometimes with spiritus mindereri, will be useful. Sponging with Epsom salt solution, one ounce to sixteen of tepid water, is grateful and soothing.

If the temperature should run high and internal congestion be present, no remedy acts so well in my hands as veratrin; a pellet of 1/125 grain every half hour or twenty minutes until an impression is made and then the interval increased according to the judgment of the physician. Intestinal catarrh may require treatment by calomel, bismuth, and pepsin, or, more often, by a tablet of the combined sulphocarbolates of zinc, sodium, and calcium (the so called intestinal antiseptic tablet), crushed for the small and difficult patients and administered in hot water or milk. The pharynx may require to be mopped or sprayed with liquor antisepticus, one part to three or four of water. The heart and lungs should be examined daily. Some patients will require a stimulant treatment by strychnine, sparteine sulphate, digitalis, wine, brandy, or ammonium carbonate, and frequently administered liquid nourishment, including beef extract or occasionally some other meat juice. Complications on the part of the larynx or trachea will be met by steam inhalations; and of the bronchi according to the state of dryness, rales, or cough present; likewise of the kidney according to the pathological condition.

During convalescence a general tonic should be exhibited of malt extract or of quinine, iron, cod-liver oil, occasionally nux vomica. Desquamation need not debar the patient from exercise out of doors under due precautions. At the close of desquamation the patient should receive a good warm bath and the underwear and night wear be put through a thorough disinfection. The régime for any contagious disease should be put in force at the outset and maintained. The nurse and the visiting physician should wear a gown in the sick room, and on leaving the room the clothing and shoes and hands should be sprayed with a disinfecting solution, as of lysol or carbolic acid. In an institution it is desirable to add a cap to the gown. Very important is rigid disinfection of the underwear of the patients. When it comes off it should be soaked in corrosive sublimate solution for an hour or more before going into the wash tub. Disinfection of the person and his clothing and bedding, especially at the end of the stage of desquamation, is decidedly indicated. When the case has terminated, the bed itself should be disinfected and the bedroom well fumigated before the quarantine is raised. Other children in the family should not be allowed to go to school until the period of incubation is over (fifteen to twenty-one days).

THE MICROSCOPE IN DERMATOLOGY.

An Aid to the General Practitioner in the Diagnosis of Diseases of the Skin.

By Oscar L. Levin, M. D.,
New York,

Consulting Dermatologist, Sanitarium for Hebrew Children, Rockaway Park, L. I.; Assistant Physician, Department of Dermatology and Syphilology, Cornell Medical School.

The skin, because of its exposed position, is admirably suited for study of the diseases which may affect it. A correct diagnosis is possible in most cases, when the observer's eye is trained and his conception of pathology is clear. Not every physician can obtain a thorough training in all branches of medicine and become an expert diagnostician, but in dermatology the general practitioner is aided in diagnosis by the exposed position of the integument

and accessibility of the abnormal products from the lesions, which may be examined in the laboratory.

It is not intended to describe the evidence which may be obtained by biopsy, by culture, or by the other complicated procedures, but to outline what may be studied by any one who possesses a microscope. These examinations, although simple, will at first tax one's patience. The technic is readily acquired and with a little practice one becomes adept.

The first disease to be considered is syphilis. An early positive diagnosis of this disease can be made by means of the microscope when the causative agent, Spirochæta pallida, is found in the secretion from the initial lesion. This organism is present, not only in the primary stage, but occasionally in mucous patches, condylomata, and the ulcerative lesions of the tertiary stage. A description of Spirochæta pallida, its differentiation from microorganisms resembling it, and the methods for determining its presence in a lesion will be given in the next number of this journal.

The chancroid or soft chancre, although not of such frequence as formerly, is sufficiently prevalent occasionally to cause confusion. Only too often do we see patients suffering from late symptoms of lues in whom the initial lesion had been called a soft chancre. This should not happen. It is desirable to examine every ulcer on the genitals, for spirochetes and the streptobacilli of Ducrey, the exciting agents of the chancroid.

This microorganism is a very short Gram negative bacillus with rounded extremities, measuring from one to two micra in length and about one half a micron in thickness. It does not form spores, is not flagellated, and is not motile. As a rule it is extracellular, but occasionally may be found within pus cells.

To demonstrate its presence, a loopful of the pus from the ulcer should be smeared on a glass slide, dried by passing it several times through a flame, and then stained by the Gram method.

A positive diagnosis of scabies may be made by finding Acarus scabiei or its eggs in the skin. A burrow is removed by shaving the skin with a razor blade. It is then floated in a drop of glycerin on a glass slide, covered with a cover glass, and examined with the low power lens. This organism is an oval or round body having four anterior legs provided with suckers and four posterior legs with bristles, and is found at one extremity of the burrow. This burrow also contains the eggs and feces extruded by the itch mite. The former are round or oval, granular bodies with a double contour; while the latter appear as irregular oval, brownish black, homogeneous masses about one half as large as the eggs.

Unna describes under the name, ringworm, various lesions produced by the activities of a mould fungus in the epidermis. These lesions are varied, their common characteristics are: 1. They cause scaling; 2, a disease of the hair leading to its destruction, or at least its temporary loss, but not, 3, the formation of scutula. This last point distinguishes the group of trichophytosis from that of favus, the second from a series of other fungus diseases (pityriasis versicolor, tinea imbricata, etc), the first from certain diseases of the hair shaft alone.

There are various conditions from which ringworm must be differentiated. On the scalp it may resemble alopecia areata, favus, eczema, seborrhea, psoriasis, and scaly tubercular syphilides. Kerion may resemble carbuncle, blastomycetic granuloma, pustulonodular syphiloderm, and tuberculosis. The superficial type of ringworm occurring on the beard bears a strong resemblance to eczema, sycosis barbæ, impetigo contagiosa, and to a lesser degree to the tubercular syphilides. The deep seated ringworm is to be differentiated from carbuncle, furunculosis, and some types of the late secondary pustulonodular syphiloderm. Blastomycosis and actinomycosis also suggest this form of trichophytosis. Tinea circinata may be confounded with favus of the general cutaneous surface, impetigo contagiosa, eczema, seborrhea, the scaling syphilides, pityriasis rosea, psoriasis and tinea imbricata. Ringworm of the palms and soles, beside resembling the diseases enumerated, also looks like the squamous syphilide. When ringworm attacks the nails exclusively, a positive diagnosis can be made only by means of the microscope. In this locality the disease may resemble chronic eczema, favus, psoriasis, or any of the atrophic diseases of the nails. Occasionally tuberculosis or syphilis may be simulated. Tinea cruris should be differentiated from eczema, seborrhea, and erythrasma.

On a special medium, Sabouraud was able to isolate more than forty strains of the ringworm fungus. He believes that individual strains are capable of producing specific types of lesions. Unna, on the other hand, professes to have seen one strain produce both vesicles and nodes. For all practical purposes, only two groups of the fungus need be studied, namely, the small spore or Microsporon audouini and the large spored variety, or Megalosporon trichophyton. The latter is again subdivided according to its relation to the hair; when within the hair shaft it is called endothrix, when outside it is called ectothrix; and when found within and without the hair, ectoendothrix.

The microsporon is more likely to occur in children, commonly on the scalp and the general cutaneous surface. When on the scalp it produces round, almost bald areas with prominent follicles covered with fine scales. The hairs in these areas are short and broken off, present the appearance of exclamation points, and when pulled come out easily. It is a fungus consisting of mycelia and spores. The mycelia when demonstrated are few in number, resemble narrow transparent tubes, and branch in all directions, but not as promiscuously as in favus. The spores are small, round, or oval, occasionally doubly contoured and granular. As a rule they are numerous and packed densely in the form of a mosaic.

The trichophyton occurs in lesions found in adults, on the beard, on the nails, and on the palms and soles, where it produces eczemalike patches. When on the scalp the trichophyton produces round or irregularly shaped patches covered with grayish white scales, often containing twisted dead hairs. It is the fungus usually found in kerion. Tinea cruris is caused by a large spored fungus, Epider-

mophyton inguinale. The megalosporon consists of mycelia and spores. The spores are two or three times as large as those of the microsporon and arranged to resemble chains of beads. The mycelia are larger and do not branch as much as those of the small spored fungus. The spores and mycelia occurring outside the hair are usually larger than those found within the shaft. Spores are found most frequently at the frayed extremities of the hair. Some of the scales and crusts contain disintegrated hairs which are always full of spores.

The demonstration of the fungus in hairs, scales, and crusts is rendered simple by soaking the material in a solution of potassium hydroxide and then examining the unstained specimen with the high power lens. Staining the specimens is unnecessary and not as clear as the simple method. In selecting hairs for examination, those should be examined which appear diseased, that is, broken off, dry, twisted, or bent, and those which emerge from prominent and purulent follicles. The hair should come away upon the slightest traction. When scales are to be examined, they should be scraped from the lesion and then cut and macerated into the finest particles.

The hair, crust, or scale is placed in a twenty-five per cent. solution of potassium hydroxide on a glass slide and a cover glass is placed gently over it. To hasten the action of the caustic alkali the specimen should be heated over a Bunsen flame until bubbles rise. The specimen may be examined immediately, but it is better to wait five minutes, as it becomes clearer. It is best to allow scrapings from nails to stand overnight in the potassium hydroxide solution. Most beautiful specimens are obtained by soaking the affected material in the alkaline solution for several days. These may be preserved by allowing glycerin to float under the cover glass and sealing the edges with paraffin.

Care should be observed not to mistake fat droplets and epithelial cells for spores. This may be prevented to a degree by washing the hairs and scales in ether before using the caustic solution. Air bubbles also resembles spores, but their number may be reduced to a minimum by the use of plenty of solution. Besides, air bubbles are usually larger than spores, more irregular, and not granular.

A typical case of favus, consisting of heaps of sulphur yellow, cupped crusts and grayish asbestos-like scales occurring on a scalp showing more or less alopecia and scarring, offers no difficulty in diagnosis. Favus does not always present this picture, however, but may appear as a moist or dry dermatitis or resemble ringworm, lupus erythematosus, folliculitis decalvans, alopecia areata, or psoriasis. All of these possess their own characteristic signs, but often a diagnosis cannot be made except with the microscope.

When making a microscopic examination of material from a favus lesion, we look for the exciting agent, a vegetable fungus called Achorion schönleinii. This fungus consists of mycelia and spores. The mycelia are long, narrow, straight, or curved grayish filaments with numerous branches which spread irregularly in all directions. The spores are round, oval or dumbbell shaped, and more elongated than those of the ringworm fungus. They are numerous and may be found easily in the affected hair or scutula. The scutula are composed almost entirely of spores. They are distinguished most readily at the loose margin of the crust rather than at the more densely packed centre.

The spores of the achorion are longer, more irregular in size and shape, more elongated and abundant than the ringworm spores. The bubbles formed by heating the potassium hydroxide solution tend to persist; whereas those formed in ringworm preparations disappear when the slide is set aside for several hours.

Chromophytosis, pityriasis, or tinea versicolor is a disease of the skin characterized by the development of variously sized and shaped spots and patches which are slightly scaly and yellowish brown in color. It is caused by the growth of a vegetable parasite, Microsporon furfur, in the stratum corneum. This disease is of particular importance to the general practitioner because of the likelihood of confounding it with a fading syphilide. It should be distinguished from seborrheic eczema, pityriasis rosea, and erythrasma. If the diagnosis is in doubt, a microscopic examination for fungi should be made.

Microsporon furfur consists of a dense network of long narrow interlacing mycelia and highly refractile spores which are larger than those of ringworm and arranged in clumps like bunches of grapes; occasionally free spores may be found. The bent pieces of hyphæ and isolated collections of spores are considered by Unna to be characteristic of this condition. The fungus is found with the low power lens in the scales and stratum corneum.

Blastomycosis, although uncommon, is found, and resembles tuberculosis verrucosa cutis, lupus vulgaris, vegetating forms of syphilis, and occasionally epithelioma, kerion, suppurations, whether follicular or not, carbuncle, and actinomycosis. A positive diagnosis may always be made by means of the microscope.

A loopful of pus from one of the miliary abscesses should be mixed with a drop of a saline solution on a cover glass and then inverted over a hollow slide. The blastomycetes are found in the hanging drop. They are yeast fungi, usually round or oval, but occasionally irregular in shape, having an outer homogeneous capsule, a transparent zone, and a central granular protoplasm containing a vacuole. They often show budding. Mycelia are found in specimens from a pure culture.

Fully developed leprosy with nodules and maculoanesthetic areas is readily diagnosed. A macular leprosy, however, may be confounded with vitiligo, chloasma, morphœa, white spot disease, or syringomyelia, and a nodular with syphilis, lupus vulgaris, multiple benign sarcoid of Boeck, or erythema multiforme. In doubtful cases an attempt should be made to find the lepra bacillus which is abundant in the nasal secretion.

The bacillus is straight or slightly curved, with pointed or rounded extremities. It stains irregularly and shows clear spaces within its protoplasm. It occurs in chains and resembles the tubercle and smegma bacilli. It differs from the smegma bacillus in not being decolorized by alcohol after staining with carbol fuchsin, and from the tubercle bacillus

by retaining the stain after immersion in cold carbol fuchsin for six to eight minutes. It is found most often in the secretion obtained from an ulcer almost always present at the junction of the bony and cartilaginous portions of the nasal septum.

Anthrax attacks the skin in two forms; in one, the more common, a malignant pustule appears, which may resemble a boil or a carbuncle, in the other an edema of the tissue occurs which has to be differentiated from erysipelas. A positive diagnosis is always urgent and the discovery of the anthrax bacillus in the discharge makes this possible. A loopful of the pus from the pustule or a few drops aspirated from the deeper infiltration should be smeared on a slide, dried by passing through a flame, and stained with the ordinary anilin dyes or better by the Gram method.

Bacillus anthracis, when found, is usually in the form of short rods with expanded extremities which are slightly concave. Threads made up of these short rods joined end to end are also observed. It is a Gram positive bacillus.

Glanders may be acute or chronic. An acute attack manifests itself in the skin by the formation of a gangrenous ulcer which may resemble a chancroid or a syphilitic ulcer and constitutionally by severe symptoms of intoxication. Chronic glanders assumes the appearance of a benign infection and on the skin produces a chronic abscess which may resemble a broken down gumma, a cold abscess, or sporotrichosis.

An early diagnosis is made by finding Bacillus mallei in the lesion. It is always difficult to find this bacillus in a smear of the pus. Nevertheless, we are more likely to find it if the loop is carried to the floor of the lesion and the deep tissues are scraped. The pus thus obtained, when smeared and stained with methylene blue, may show the bacillus.

This bacillus is a rod with rounded or pointed extremities. It stains irregularly with the ordinary anilin dyes. A satisfactory stain is always difficult to obtain because it is decolorized so rapidly.

In writing this paper an attempt has been made to point out the value of the microscope in the diagnosis of the more common diseases of the skin. Anthrax, glanders, blastomycosis, and leprosy, although uncommon, are seen occasionally and are therefore included. The microscope may also aid in the diagnosis of rare diseases, namely, sporotrichosis, actinomycosis, mycetoma (Madura foot), filarial elephantiasis, Dhobie itch, tinea imbricata, erythrasma, and pinta. There are several diseases of the hair in which a microscopic examination with the low power lens is indicated. These are monilethrix, trichorrhexis nodosa, piedra, and tinea nodosa. It is emphasized that in dermatology, as in any other branch of medicine, the microscope is used mainly for corroborative evidence.

CONNELLAN-KING DIPLOCOCCUS INFECTION OF THE TONSIL.*

Its Relation to Arthritis.

By James Joseph King, A. B., M. D.,
New York,
Attending Laryngologist, Hospital for the Ruptured and Crippled; Assistant Surgeon, New York Eye and Ear Infirmary; Etc.

At the Hospital for the Ruptured and Crippled we have been greatly interested in focal infections, especially in the tonsils and teeth, and the relation of these infections to arthritis. It is now generally accepted that most patients with septic arthritis or conditions that were formerly classified as rheumatism have a focus of infection somewhere else in the body. In many such cases I have treated the infection in the tonsils, eradicated it by the use of autogenous vaccines, and later, in most instances, enucleated the tonsils with gratifying results.

About two years ago we noted the frequent presence of a Gram negative diplococcus in the crypts of the tonsils in such cases. An autogenous vaccine was prepared from this microorganism and used in these early cases with brilliant results. For lack of a better name this Gram negative diplococcus has been called the Connellan-King diplococcus. Doctor Gibney has asked me to describe some of the cases that we have treated by these vaccines and enucleation of tonsils.

Case I. J. M., a boy, aged thirteen years, was referred to me two months ago. His family and personal history were unimportant, except that he had had two attacks of tonsillitis in his life, one five years ago and the last one four weeks ago. For about six months he had complained of pains in both feet and ankles. A short time before the pains in the feet started he turned on one of his ankles while playing baseball.

When he first came to me, both ankles were much swollen and the pains in the feet and ankles were considerable. A culture made from the crypts of the tonsil showed the Connellan-King diplococcus, from which an autogenous vaccine was prepared. The boy was given 100 million of the vaccine by hypodermic injection, every second day, until he had received eight or nine injections. By this time the pains and swelling in the feet and ankles had disappeared. No other treatment was given.

On November 20, 1915, his tonsils were enucleated at the New York Eye and Ear Infirmary. He made an uneventful recovery.

Case II. E. W., aged twenty-nine years, still under treatment, was referred to me about one month ago for the consideration of his tonsils and a possible connection with an osteoarthritis of the right hip. He gave no history of tonsillitis.

On July 5th, after a game of golf, he first noticed pain in his right hip, and he did not recall any trauma at the time which might have caused it. He went about as usual for two weeks without treatment. Then his doctor prescribed counterirritants, and kept him at home and in bed for one week. He then went to Nassau Hospital, where he was kept in bed with Buck's extension on for three weeks, during which time he was given remedies for rheumatism. After leaving the hospital he felt better and was able to get about with a crutch and stick. He soon gave up the crutch and could walk fairly well, but limped and tired easily.

When I first saw him, in November, he complained of pain in his right hip and walked with a little limp. Doctor Gibney had found little impairment of the function of the hip. The x ray plate showed an osteoarthritis of the right hip. A culture made from his large and cryptic tonsils showed the Connellan-King diplococcus.

This patient is now receiving autogenous vaccine

*Presented before the third annual meeting of the Alumni Association of the Hospital for the Ruptured and Crippled, New York, December 18, 1915.

and thinks he is improving. His tonsils were enucleated at the New York Eye and Ear Infirmary on December 20th. It is too early yet to tell what will be the final result on his hip, but he has improved markedly in a general way since his tonsillar infection was cleared up with the vaccines, followed by tonsillectomy.

Case III. Miss E. S., aged twenty-six years, was reported before the New York County Medical Society on October 26, 1915, and her story was published in the *Medical Record*, December 4, 1915. She was first seen by me in consultation, July 26, 1915. She had an attack of tonsillitis five and a half years ago. One month later, arthritis developed in feet and knees, which was progressive in spite of almost constant treatment, including four or five trips, each of one month's duration, to Mount Clemens. Examination: Joints of hands and knees much swollen and deformed, and continual pains in them. Valvular disease, with a distinct mitral regurgitation. Tonsils moderate in size, purplish in hue. Culture from them revealed Conellan-King diplococci. She was treated with the vaccines by her physician, with great improvement. On September 8, 1915, I enucleated the tonsils at the New York Eye and Ear Infirmary. She made an uneventful recovery.

This patient's joints are now almost normal in size and free from pains. Her heart murmur persists, but is softer in character, and I believe improved. Her color and general appearance are greatly improved.

The following tentative conclusions have been drawn from the observations made in about 100 cases:

1. Every case of septic arthritis, commonly called rheumatism, is caused by a focus of infection somewhere in the body. It may be found in the tonsils, ears, accessory sinuses, gastroenteric tract, genitourinary tract, or in and around the teeth.

2. The most frequent focus is found in the mouth and the tonsils, on account of their crypts, harbor the focus more frequently than any other gland or organ.

3. A very simple tonsillitis may be followed by complications—nephritis, endocarditis, myocarditis, arthritis—so serious as to endanger life.

4. The infection may become latent and produce serious trouble weeks or months later at a point far removed from its original site.

5. In view of an occasional general sepsis coming on after a tonsillectomy, it is necessary, where possible, to clear up the infection with autogenous vaccines before operation. In this way the danger of a general sepsis following tonsillectomy is eliminated.

6. Where the focus of infection in arthritis exists in the tonsil, the treatment should consist in the injection of autogenous vaccines until all infection is cleared up, and then the removal of the tonsils by enucleation.

7. The complications in this infection are caused by an absorption of chemical toxines rather than by a bacteriemia.

8. In the Connellan-King diplococci infections the blood changes seem to be a simple anemia and in a few cases a slight increase in the number of eosinophiles, four to six per cent.

9. In some cases symptoms other than those for which treatment was instituted have disappeared. For instance, in one patient with arthritis and marked ethmoiditis the culture was obtained from the throat. After two weeks of treatment the arthritis was only slightly improved, but the ethmoiditis and pus in the nose had entirely disappeared.

10. The treatments with the vaccines have been eminently satisfactory in a high percentage of the cases treated.

MAYER'S SOLUTION.

A Noncaustic Hypochlorite,

By Douglas H. Stewart, M. D., F. A. C. S.,
New York.

More than ten years ago, both laboratory and clinical experience united to teach the writer of this communication that freshly made acid solutions of the hypochlorites were better than the alkaline ones. But every day use of the latter upon wounds and upon surgeon's hands was proof of a value so considerable that reemployment after abandonment has now become a surgical habit; and this despite such handicaps as irritation or even cauterization, an odor which suggests cesspools, and a constant search for something better, less irritant, and with a lower degree of offense to the nostrils of the neighborhood.

Experimentation with acids, solid or fluid, and comparison of many solutions resulted in the selection of vinegar and of alum, as the most convenient representatives of their respective types. Alum had the advantage over boric acid, of higher acidity and of withstanding the destructive powers of boiling water. Renewed trial confirms the opinion that there is nothing superior to aluminum sulphate for acidulating hypochlorite solutions. For such a purpose it stands as high among the solid acids as does vinegar among the liquid.

France has given us the *eau de Javelle*, which was first made at the mill of Javelle, whence its name, Javelle water, corrupted by washerwomen into the colloquial javlin water, termed by the *National Formulary* liquor potassæ chlorinatæ. The same country has named liquor sodæ chlorinatæ for Labarraque, who first brought it to public attention, and now Charles Mayer, in *Paris médical* for February 19, 1916, sends us his experience with magnesium hypochlorite. If the reader will term this Mayer's solution, or name the liquid liquor magnesii chlorinati, and will consult either the original record or the excellent abstract published in the New York Medical Journal for April 29, 1916, page 854, repetition will be unnecessary and this brief essay will be free to limit itself to the results obtained by clinical trial (250 applications).[1]

The first step was the proper one, preliminary to any clinical proof, viz., a verification of the facts, and the writer feels that he went far enough into that matter to be very sure that he may corroborate the essentials of the *Paris médical* article. As the trial itself progressed, it became more and more evident that the method of preparation could be im-

[1]Mayer prepares his solution by bringing together 190 grams of magnesium sulphate and 100 grams of calcium chloride, each previously dissolved in two litres of water, and filtering the resulting mixture in order to remove the precipitated calcium sulphate. To secure an absolutely clear solution, complete deposit of the precipitate must be awaited and the overlying clear fluid decanted. New York Medical Journal, *loco cituto.*

proved and simplified. The result of following Mayer's method is a precipitate of gypsum, or wet plaster of Paris, or calcium sulphate, call it which you will. It is fine, smooth, and free from grit; that is, it is of no medicinal value and in a wound is an inert foreign body, making necessary decanting or straining or scrupulous care in employing only the supernatant solution. But if five parts of calx chlorinata, ten parts of Epsom salts, and a heavy glass microscope slide are wrapped up in a single thickness of gauze which is securely tied with thread, and the whole package is dropped into one hundred parts of vinegar, then in one hour the solution is ready for use. In an emergency a level teaspoonful of the lime, a heaping teaspoonful of the salts may be put into a tumbler and four ounces of vinegar poured upon them, and the whole allowed to stand for fifteen minutes, or longer, and if then strained, it may be used ad libitum, either in full strength or diluted with an equal quantity of water. It may be applied with a wad of toilet paper for cleansing purposes, but cuts and lacerations should be filled with it by means of an eye dropper, which may be allowed to float in the tumbler except when in actual use.[1]

At first bandages and wipes were soaked in the solution and were applied as wet as possible, but attempted removal proved them to be adherent two days after such application. They were no worse than the usual bandages or compresses, perhaps, but the patients were educated to expect nonsticking dressings, and this anticipation and its disappointment brought about the following technic: 1. The solution was applied without stint; 2, castor oil was applied to all the dressings which came in contact with the wound. This was selected because of the excellent results obtained from some experiments with chlorinated castor oil. These, together with some curious matters connected therewith, might prove interesting, but they are foreign to the present purpose. If castor oil was not at hand, carron oil was a fair substitute. Bandages fried in deep lard, like doughnuts, were ideal, but troublesome to prepare. Ointments were bad. Drainage and similar matters lost none of their importance. In fact, just why an antiseptic should be expected to take the place of drainage is rather beyond comprehension. One thing was even more inexplicable; occasionally wounds that did need drainage would sometimes heal after Mayer's solution had been injected with a small syringe into all their pockets.

Physicians who will not or cannot sterilize their own fingers may find comfort from this hypothetical question and its answer. Suppose we were obliged to treat thirty septic wounds and that we used the usual hospital method of hand cleansing with a sterile rubber glove for covering. Suppose again that on the opposite hand, after an ordinary wash off, was drawn a good cotton glove and that hand and glove were held in Mayer's solution for two minutes or until they were well wet. And suppose finally that we proceeded to treat the aforesaid thirty septic cases with one hand gloved with rubber and dry, and the other hand cotton-gloved and wet with a powerful germicide such as the Liquor Magnesii hypochloriti—which hand would come through the ordeal with the fewest pathogenic organisms upon it and which glove would, if uncleansed, be the safest to use upon subsequent wounds? The answer of the Petri dish is exactly what we should expect. The rubber glove never proved to be sterile, nor did the hand which it covered, unless some means had been employed to check perspiration. Pus and wound secretions could be put upon the dorsum or the palm of the hand, and if the cotton glove was kept wet with the solution, then both glove and hand would be found sterile, or at least the word "vigorous" would be quite inapplicable to any culture growth which could be obtained from the germ cargo.

Three things stood out prominently, in this preliminary trial, as attributes of Mayer's solution:

1. Its ability to stimulate scab formation.
2. The small size of the scars obtained from large wounds and the increased speed of healing in previously sluggish septic conditions.
3. The simplicity of extemporaneous preparation. Chlorinated lime, Epsom salts, and vinegar are obtainable at almost any feed store or grocery, to say nothing of a drug store or a department store.

Not the least of its good qualities is the way it will deodorize bad smelling shoes or septic vaginæ. At the same time its own odor is slight and not to be compared in offensiveness with that of the ordinary alkaline mixtures of the hypochlorites.

The writer has had his hands in the aforesaid magnesium liquid for an hour or two, day after day, and cannot discover that the epidermis is damaged nor has anything more than trivial eczema appeared upon the skins with which he brought it in contact. Much more irritation, from eczema or dermatitis, is occasionally found after the application of the sodium citrate-normal salt solution than has as yet appeared from the use of liquor magnesii chlorinati.

A demonstration is always of value. He who wishes to witness one may bind any other solution of five per cent. calx chlorinata upon his right arm, and this one may be bandaged upon his left. His judgment will not waver long in deciding his preference for one of the two, nor will there be any doubt in his mind for some hours after the bandages are removed.

128 West Eighty-sixth Street.

[1] If time permits, take chlorinated lime, one part, acetic acid, 80 per cent., 1 5 part, and add Epsom salts, two parts, previously dissolved in twenty parts of water.

Relation of Gout to Nephritis.—Morris S. Fine (*Journal A. M. A.*, June 24, 1916) makes a study of uric acid concentration in the blood of cases of typical early gout and of early interstitial nephritis and shows that in both conditions the earliest abnormality was an increase in this acid. Determinations of the urea nitrogen, creatinin nitrogen, the phthalein output and the systolic blood pressure in these cases gave results which were strikingly parallel for the two groups. So close was the parallelism that he questions: Is gout only a stage in the development of interstitial nephritis? His observations point to the value of determining blood uric acid as a means of early diagnosis of gout in otherwise doubtful cases, and also to the danger of erring in diagnosis between very early gout and very early interstitial nephritis.

Abstracts and Reviews.

CONSERVATIVE SURGICAL CORRECTION OF RETARDATIVE DISPLACEMENTS OF THE COLON.

By Charles A. L. Reed, M. D.,
Cincinnati.

Dr. Charles A. L. Reed, of Cincinnati, at the recent 1916 Detroit meeting of the American Medical Association, discussed constipation due to various forms of mechanical conditions in the intestines. Measures for their relief, he said, were radical and conservative. The radical operations were short circuiting and excision, or a combination of both. They were indicated when no other procedure would reestablish physiological drainage of the intestines. Conservative operation consisted in fixation of the displaced colon to relieve retardative angulation and mechanical interference with circulation. The operation devised by the speaker was called parietal implantation of the colon.

The essential steps of the procedure were as follows:

Lower zone of the abdomen: 1. Make a median incision from near the umbilicus to near the pubes.

2. Explore the viscera preferably in the following order: *a*, cecum; *b*, appendix; *c*, first twelve inches of the terminal ileum; *d*, ascending and transverse colon; *e*, stomach; *f*, sigmoid; *g*, proximal intestinal surfaces; *h*, pelvic viscera.

3. Break up any adhesions that may be found.

4. As far as possible, correct all peritoneal abrasions that might have been made by breaking up adhesions, giving particular attention to those which might have resulted in exposure of the muscularis of the intestines.

5. Approximate the peritoneal margins and hold them together with hemostatic forceps, until all work in the upper zone of the abdomen had been finished.

6. If there had been adhesions, particularly if numerous or extensive, put a litre of hypertonic salt solution into the peritoneal cavity before completing closure of the lower incision.

Upper zone of the abdomen: 1. Make an incision transversely across the intercostal interval about three fourths of an inch below the tip of the ensiform cartilage, extending the same incision at an obtuse angle downward and to the right about a half inch below the costal margin for a distance of from five to six inches.

2. The incision just indicated divides, *a*, the integument; *b*, subcutaneous fat; *c*, superficial fascia; *d*, inner half of the left rectus; *e*, all of the right rectus; and, *f*, the inner margins of the external oblique, internal oblique, and the transversalis muscles, and, finally, *g*, the transversalis fascia through the entire length of the incision, care being taken not to extend the incision along this line through the peritoneum.

3. Begin at the epigastric fat and dissect the peritoneum away from the transversalis fascia for a distance of three quarters of an inch along the whole length of the incision.

4. Evert the lower flap by seizing the transversalis fascia at several points with deep bights of hemostatic forceps.

5. Divide the peritoneum and the ligamentum teres along the lower line of denudation and bring the ligamentum teres out through a puncture at the base of the peritoneal flap.

6. Explore the upper zone, particularly with reference to the stomach and duodenum, giving special attention to the frequently enveloping exudate, the gallbladder, and the pancreas.

7. Put the patient in the Trendelenburg position, bringing the transverse colon and omentum out through the incision.

8. Fasten the omentum to the denuded transversalis fascia by stitching the base of the former by its external surface, to the lower margin of the denuded surface of the latter, employing a continuous interrupted suture and exercising care to avoid wounding or constricting important omental vessels.

9. Close the wound by the following steps: *a*. Stitch the margin of the upper peritoneal flap to the under surface of the transversalis fascia. *b*. Approximate the divided ends of the muscles by continuous interrupted sutures of chromic gut passed through the superficial fascia, muscle, and transversalis fascia. *c*. Fortify the last line of sutures with a few silkworm gut sutures passed through the fascia, muscle, and skin. *d*. Close the skin according to the operator's usual method, that employed by the writer being preferably the continuous buttonhole stitch with fine catgut.

The speaker reported 226 consecutive cases of parietal implantation without a death, and sixty-two cases in which the operation was combined with other procedures, with six deaths. The results, so far as functional restoration with consequent good health was concerned, were reported to be highly satisfactory. Demonstrations by x rays were presented, showing the implantation intact after more than five years.

Contemporary Comment

Medical Aspects of the Mexican Situation.—The great European war has now lasted for nearly two years, and to the ordinary perception there is no immediate indication of it ending, says the *Boston Medical and Surgical Journal* for July 6, 1916. Though many persons feel, or at least express, confidence in the manner of its termination, to impartial observers its outcome still seems as much as ever on the knees of the gods. Naturally, as members of a dispassionate profession and citizens of a neutral country, American physicians, whatever their personal sympathies, have been largely interested in the medical aspects of the great war. . . .

The United States is now menaced, more acutely than at any time since April, 1914, with the incidence of a second Mexican war, which at the present writing seems likely of declaration within a short time. In the several States throughout the Union during the past week, the militia, or national guard, has been mobilized, with the demonstration of varying degrees of efficiency and preparedness. A num-

ber of these militia units have already been dispatched to the Mexican frontier. Whether or not this mobilization proves to be the precursor of actual war, the Mexican situation is not only of intense concern to all Americans, but in its medical aspects affords to the American profession matter of import for action, as well as observation. The occasion and opportunity have arrived when the medical corps of the army and navy, the medical officers of the national guard, and, in the event of extensive hostilities, civilian members of the profession will either demonstrate or fail to demonstrate their fitness to deal competently and creditably with the medical urgencies that arise in time of war; and it is most earnestly to be hoped and expected that this demonstration will be in every respect a credit to the American profession. . . . Unlike law, medicine speaks with an even stronger and more authoritative voice in times of war than in times of peace; and in Mexico, as well as in Europe, the work of our profession will be not only to succor the injured, but to maintain the standards and purposes of civilization through the inevitable barbarisms of war.

The Conquest of Syphilis.—Under this head, *Northwest Medicine* for April observes: "Greatly as mankind has benefited through the newer tests for syphilis, they have not been without harm. Many of the patients treated with one or two doses of salvarsan when that treatment first came out, with promise of complete cure, have neglected other treatment and are now returning, often with thoroughly established syphilis of the internal organs or of the nervous system. There is little good introduced into this vale of tears that is entirely free from evil. And so, not only has salvarsan therapy been abused, but its diagnostic congeners, serology and spinal puncture, have also been badly used. Sometimes through scientific zeal, sometimes through commercialization, these worthy adjuvants to the practice of medicine have done considerable harm. As a result of too enthusiastic acceptance, especially of the recent vaccine tests, there is great danger that many persons will be pronounced syphilitic on exceedingly doubtful evidence. This is especially true of congenital syphilis, in which the exploiters and purveyors of luetin teach that positive reactions are practically certain, notwithstanding that there may be no clinical evidence to substantiate them in a given case. That luetin and possibly other skin tests may react positively in the presence of syphilis is not disputed. The danger is that they may react where no syphilis is present. The tests are fairly delicate and in reading the results the differences between positive and negative findings are inconsiderable. A multitude of accidents may enter into the reaction, such as infection, constitutional dyscrasia, etc. It must not be forgotten that many laboratories are presided over by enthusiasts who have had little clinical training and who lack any aptitude for that kind of training. They discover, the clinician must apply. Exuberant claims are seized upon by the commercial world, advertised and lauded in season and out, with results that at times seem more than risky. Until absolute proof is forthcoming, these tests should be accepted and used cautiously and, unless backed up by other evidence, should be taken with great reserve, lest they bring fear, doubt, and unnecessary treatment into the lives of persons who do not deserve such affliction. If in the fullness of time they shall be proved as certain, they will benefit humanity, but until absolute proof is forthcoming they should be accepted in a conservative spirit worthy of scientists. Taking in its entirety, the problem of syphilis is being solved. Sanitary and moral prophylaxis go hand in hand with better diagnosis and better treatment and offer hopeful prospects of a complete conquest of the scourge."

Cancer of the Skin.—During the ten years ending with 1909, out of every 100,000 deaths in the United States, 918 were due to cancer of the skin. Two per cent. of all skin diseases are cancerous. This state of affairs is certainly susceptible of vast improvement, as a result of the conscientious efforts of the whole profession to recognize and remove precancerous lesions of the skin; and to teach their patients the doctrine of early removal of suspicious lesions. Thus the *Journal of the Florida Medical Association* for May, 1916, in some notes credited to the American Society for the Control of Cancer. The notes continue:

Cancer here as elsewhere never begins in a healthy area of skin, but has as a warning of its approach one of the precancerous lesions, which is usually present quite long enough to give ample time for its recognition and removal. The skin, being in plain view, offers unusual advantages for frequent inspection of a suspicious area and unusual opportunities for the safe, simple, easy, complete, and inexpensive removal of its potential cancers; therefore every death from cancer of the skin is a monument to carelessness or procrastination on the part of the physician or the patient, or both.

Some of the usual precursors of cancer of the skin are:

1. Pigmental moles, the kind which are deeply pigmented, and slightly raised above the surface of the skin. These are especially dangerous if they occupy an area which is constantly irritated by the clothing, shaving, etc.

2. The dark, dirty looking, warty growths of the exposed surfaces of the skin of those past middle life. These are the so called senile warts, about five per cent. of which become cancerous.

3. Small lumps in or just under the skin, remaining a long time, are frequently beginning cancers. They are at least never normal, and act as an outstanding invitation to cancerous development.

4. Unhealed ulcers, which have persistently resisted ordinary treatment for a few weeks, with the exception of varicose and syphilitic ulcers, should be looked upon as possible grave enemies to their hosts, and should be got rid of at once.

These and other localized areas of chronic skin lesions are so very apparent, so easy of complete and painless removal by the knife, under local anesthesia, and so frequently the sites upon which cancer later develops, that the physician is untrue to his patient and himself who does not take a definite stand in urging their removal in the early, precancerous stage.

THE PARALYSIS SCARE.

We intimated in our issue for July 8th (page 77) that the present endemic of infantile paralysis was by no means so terrible a thing as the first newspaper reports made out. The disease has been with us annually for many years, and has taken its toll in death and disability. It was always thought to be a hot weather disease and usually invaded the city in August; it came early this year, and after cool weather, and seems to have greatly impressed some one new either to office or to sources of publicity. When we compare the results of our annual visitations of croup and diphtheria, the latter with its postdiphtheritic paralysis, we are moved with difficulty to regard as serious the invasion of anterior poliomyelitis. Nature may have concluded that the legs of New Yorkers, especially in movements toward civic cleanliness, were becoming obsolete, and have therefore decided gradually to eliminate them. The plague seems to have reached its height and to be already abating; but we hope that a lesson in cleanliness has been taught. Already myth had begun to hover about the attack; for example, the second submarine boat from Germany is to bring us a specific treatment, probably to heap coals of fire on our heads. The board of health is reported to be working along with the Rockefeller Institute on a new serum. It was about time that the authorities awoke to a disease the treatment of which has not varied for over a quarter of a century.

PHYSICAL STANDARDS FOR THE RECRUIT.

To the medical man the most significant feature of the recent unfruitful attempt to bring the army up to its full strength is the disproportion between the number of applicants and the number rejected because they were not up to the physical standards set by the army. The as yet incomplete returns, while the number of the applicants is not small, point to an acceptance of less than ten per cent. This condition may mean either that the applicants as a class represent the physical standards of the country, which are, therefore, wofully poor; or that the physical standards placed for the military arm of the government are unusually high. If the rejections are due to the low physical standards of the people at large, then the matter is, indeed, of grave significance—and radical measures must be devised to bring the citizenship up to effective standards. Either all individuals of school age and school attendance must have forced upon them systematic physical training of the ordinary or of the military variety, or there must be compulsory military training some time after the school age. In the last analysis military training is but physical training with a purpose.

With the advance of civilization, with its machinery and its labor saving devices—with the ease of living added, there is an ultimate tendency to disuse of the muscles and their consequent atrophy. There is a devolutionary change in the muscular system inimical to the physical standards of the race. Any form of training that would develop the muscles, or recreate the habit of their use would redound to the benefit of the race. Individuals with good development of the muscles find a positive pleasure from their use, while to those undeveloped nothing is more irksome. It is the adversity to which a species is put or the amount of use to which its powers are put that produces the resisting qualities necessary to the survival of the fittest. A nation whose physical standards become greatly reduced, must give up its place among nations.

On the other hand, if the number of the rejections for military service is due to the rigidness of the physical requirements, a rigidness exceeding actual necessity, then these must be revised in order to give volunteers the advantages of this training and the people the benefit of the service of those fitted for them. There must be a determination between the physical deficiencies due to occupational, postural, or hygienic, and therefore correctable conditions, and those which are substantial and go to the very

root of army efficiency. In the former, it is military life which they need to bring them up to the standard; the admission of such defectives would be the means of reclaiming a class of people who now form a great part of the inefficient citizenship of every community. The medical examination would often be the means of calling attention for the first time to the presence of correctable defects at the bottom of previous inefficiency. The maintenance of even a very large army might be justified if it trained a defective citizenship into an effective one.

Physical training encourages pride in physical development. It is an achievement well worth more effort than is now expended on it. Military training engenders a care of the body at least as particular as the care given to military equipment. Physical development is the basic factor in preventive medicine. The incidence of disease varies under all circumstances, in any community, according to the physical development and the resisting power of the inhabitants.

THE ROENTGENOGRAPHIC DIAGNOSIS OF EARLY PULMONARY TUBERCULOSIS.

Many clinicians are not aware of the progress in the many fields of röntgenology. American workers hold a prominent place; to mention Case, Cole, Carman, George, Pfahler, Crane, Dunham, Hickey, and Caldwell in the United States means the omission of other excellent workers in this specialty. It is generally recognized that the x ray is practically indispensable to give a definite picture of what is going on within the lung, to back up the clinical findings, and to help in the early diagnosis of tuberculosis. For the past six years or more Kennon Dunham, of Cincinnati, has been devoting his energies to the study of the röntgenographic findings in pulmonary tuberculosis, especially in its earliest stages. In 1911, the *Bulletin of the Johns Hopkins Hospital* contained papers on this subject by Dunham, Boardman, and Wolman. Dunham's ideas seemed so radical that acceptance of them was declined by many of his colleagues. Dunham did not permit this to dampen his ardor. He went ahead with his work, and his latest standpoint is given to us in the *American Journal of Röntgenology* for March, 1916. In his X Ray Examination of the Chest for Pulmonary Tuberculosis, just issued in Kelly's well known stereoclinic series, we may study the stereoröntgenographs reproducing various tuberculous conditions of the chest. The discussion still going on in röntgenological circles should not prevent us from carefully considering Dunham's views, since they can no longer be ignored by the average clinician. We give the gist of Dunham's findings.

He declares that the treelike shadows seen in ordinary chest plates are made up of the artery, the bronchus, the vein, the lymphatics, and their connective tissue. The artery and bronchus proceed from the roots to the periphery of the lung, often so close together as to interweave or overlap, each of the structures being accompanied by its lymphatics. A larger vein follows each main bronchus, but is situated at a considerable distance from it when compared with the artery which very closely follows all the branchings of the bronchial tree. This is the normal condition.

Now, in pulmonary tuberculosis, there are characteristic abnormal changes or densities of these linear markings or treelike shadows, which reach the periphery, are more or less fan shaped with the apex toward the hilus, and are characterized by a lack of homogeneity, since each trunk has distinct and characteristic markings. Dunham believes these abnormal densities in the linear markings to be due to tubercles situated along the bronchial tree, the linear markings representing the branches of the larger bronchi and their vessels (which latter two structures form the trunks). The spread of tuberculosis thus seems to be along the main trunks or bronchi, the tubercles forming along this pathway, and, even when still quite small, breaking into the bronchi which thus drain these minute cavities.

Dunham argues that although the early individual tubercles are too small to be seen röntgenographically, we can mark the results of their dissemination along the bronchial tree, extending in a fan shaped or cone shaped fashion from hilus to pleura, increasing the density of the lung tissue in these regions, and so changing the normal linear markings that they are "blotted out by a cloud effect" or "obscured by mottling and studdings" or "a heavy density over the entire area penetrated by the markings from several trunks." In fact, the author insists that if stereoscopic chest plates are well taken, they will show tuberculous disease when the clinician fails to secure signs of this condition by physical examination.

It is necessary to make a careful study of röntgenographs of normal lungs in order more easily to detect abnormal signs. It may be stated that although by the use of the röntgenograph little indistinct spots of increased density about the root of the lung can be detected before clinical examination determines their presence, still, according to some workers in this field, we cannot, in the present state of our knowledge, assert with positiveness that this means tuberculosis until the progress of the case definitely proves it.

The opponents of Dunham's interpretation of his findings assert that such spots may be due to inflammation of any sort, not necessarily of a tuber-

culous nature. It is also necessary to prove that such findings indicate active and not inactive tuberculosis. As already mentioned, one group of workers insists that we cannot or should not diagnose pulmonary tuberculosis until definite tubercles can be seen in the röntgenograph. Clinicians as well as röntgenologists have split into two camps on this issue. There is an increasing tendency, it seems, to accept Dunham's findings and his interpretations. At any rate it is certain that before long the question will be fought out and settled one way or the other.

No matter what the ultimate decision may be in this matter, there is no question that Dunham has done truly wonderful, intensive work in his chosen field. One important point is that we should not fail to make the examination and study by the stereoscopic method. This is emphasized by all who have had experience in röntgenology of the chest. The history of the patient is most important to determine whether or not the process in the lungs, as discovered by x ray, is active or inactive.

THE ETYMOLOGY OF DIABETES.

Some lexicographers have derived our word diabetes from the Greek διαβήτης, a pair of compasses, on account of the attitude presumably taken very often in the twenty-four hours by sufferers from the disease. Dr. Robert Saundby, of Birmingham, writes to the *British Medical Journal* for June 24, 1916, to remind such etymologists that an erect and straddling attitude would be regarded as distinctly indecent by all oriental peoples, among whom a squatting position is universal when urinating. Despite the opinion of the distinguished former president of the British Medical Association, when we recall that Latinists used the word diabetes for siphon (although *sipho* was also in use), it is difficult to escape the conclusion that the word came to be applied to the disease through the exercise of a sense of humor on the part of some onomatologist of the middle ages. Doctor Saundby, however, characterizes all efforts to trace the origin of the name to be mere guesswork.

GASTROINTESTINAL STASIS.

The last word has not been said as to the causation of gastrointestinal stasis, by this term meaning an atonic condition of the digestive tract which impedes the passage of the intestinal contents, particularly in the stomach, the duodenum, the ileocecal region, and the colon. The views of Arbuthnot Lane are well known. In brief, Lane teaches that the delayed passage is due to an atonic intestine dragging on peritoneal bands, a condition which results in the formation of obstructive kinks in the lumen of the intestine. For this condition he advocates radical surgical treatment.

In contradistinction to Lane's view is the theory more recently propounded by Keith and Alvarez, who have applied modern ideas of cardiac physiology to the gastrointestinal tract. Keith (*Proceedings Royal Society of Medicine,* October 15, 1915) ascribes the fault to defective innervation. He describes six nodal areas of the gastrointestinal tract corresponding to certain "definite aggregations of myenteric plexus." These nodal regions he locates at the junction of the esophagus and cardia, the pylorus, the third portion of the duodenum, the junction of the jejunum and ileum, the lower extremity of the ileum, and the distal colon. The section of the plexus corresponding to each node, Keith believes, regulates the rhythmic contraction of its musculature. A disturbance of rhythm in one zone is capable of producing similar disturbances in adjoining zones.

On examination of specimens from operation and autopsy, Keith found that there were gross pathological changes in the nerve fibres of Auerbach's plexus corresponding to his nodal areas. These structural changes he considers sufficient to account for the intestinal disorder and alimentary stasis. He states that the stasis occurs in parts adjacent to the nodal zones.

Still more recently, McClure (*loco citato,* February, 1916) has discussed the subject, and is inclined to consider Lane's peritoneal bands and Keith's structural changes in the plexus of Auerbach alike as late events in the process and secondary to a low grade of inflammation caused by bacteria or toxins passing through an atonic intestinal wall. He believes that intestinal stasis without infection may exist for a long time and give no symptoms but constipation. McClure does not hold that stasis must always precede infection, however, as he states that infection may often give rise to stasis in persons predisposed to disturbances of innervation in the alimentary tract. He finds certain definite skin areas corresponding to the nodal areas of Keith and Alvarez, stimulation of which leads to reflex stimulation of the nodal areas of the intestine, and he points out that appropriate stimulation of the reflex skin area thus becomes a valuable mode of treatment in intestinal stasis.

None of the theories thus far described can be accepted as final, but each has an undoubted measure of truth. The theory of Keith and Alvarez has much to commend it, and if McClure's observations can be placed on a sound practical basis by abun-

dant confirmation, it will make a distinct contribution to our understanding and treatment of gastro-intestinal stasis.

WHITE GANGRENE.

Major A. J. Hull, F. R. C. S., R. A. M. C., communicates to the *British Medical Journal* for May 27, 1916, a note on a form of gangrene seen only in the lower extremity. In addition to gas gangrene and gangrene due to direct interference with the blood supply, writes Major Hull, septic gunshot wounds may be attacked by a very acute infective process which is a form of gangrene. The condition appears to be an acute streptococcal infection, and is, in appearance, not unlike phlegmasia alba dolens, but is attended by the local circumstances associated with gangrene and the general effects of an acute toxemia. The skin is glazed and white, moist, cold, and pits on firm pressure. A firm edema is present, and the distal pulse in the limb cannot be felt. The glazed white appearance of the distended skin, instead of the usual redness, seems particularly characteristic. Early in the condition the patient is extremely ill, with clammy, sweating face, and running pulse. The condition is usually fatal, and death occurs in about twelve hours. The infection is so rapidly fatal that little change in the color of the limb has been noticed. In patients who have survived somewhat longer, it has been found that during the last few hours the limb has become mottled black and the discharge exceedingly foul. No gas has been noticed in the discharge, and no crackling has been detected in the tissues. The appearance is somewhat suggestive of deep seated pus, owing to the tension of the skin, but, on making an incision into the limb, the wound merely oozes serum. In the more severe and extensive forms the infection is so severe and the patient's condition so serious that no treatment appears practicable. Amputation gives the only chance of recovery.

THE PREVENTION OF TRENCH FOOT.

The importance of this condition leads J. G. Blackman, of Portsmouth, to record, in the *British Medical Journal* for June 10th, the fact that in all the cases which have come under his observation in a small relief hospital the men confessed to being the subjects of sweating feet. Other factors are doubtless involved, but it is easy to conceive that the accumulation of this sweat, under conditions of warfare, would soon swarm with bacteria and become highly irritating to the skin and subcutaneous tissues. It would be interesting to observe whether trench foot selects the subjects of hyperidrosis. To prevent or mitigate the localized hyperidrosis Mr. Blackman has found the following treatment useful, in addition to the daily foot bath and change of socks: 1. Painting the feet with a forty per cent. formaldehyde solution. 2. A dusting powder composed of French chalk and zinc oxide, rubbed down with a few drops of formaldehyde and applied to the feet and inside of the socks. 3. A generous diet containing plenty of nitrogen.

INFANTILE PARALYSIS.

By Beverley Robinson, M. D.,
New York.

During the last few days New York has been much alarmed by the number of cases of acute anterior poliomyelitis. The epidemic is of virulent type and its extension and duration are uncertain. There is no trustworthy remedy in the acute stage, and isolation is evidently the main dependence of the health board. Many deaths have already occurred and we know well what the future of many who survive will be. Too frequently they will be more or less crippled and have very imperfect use of the lower limbs.

The infectious nature of the disease is now widely recognized. Further, it is known that a third person may carry it, although at the time he may be perfectly well so far as symptoms go.

The only remedy thus far accepted is hexamethylenamine in frequently repeated doses. Its value, however, is not great, and even during the time of its taking, the disease has broken out. It behooves us to seek for something better.

I suggest to all physicians the use of ammonium salicylate, in frequently repeated doses. The dose should be, for a child two or three years old, from one to two grains every two hours. After twenty-four or forty-eight hours the dose should not be given so frequently.

The remedy advised has hitherto been little employed. I am confident from what I have observed of its great utility in the treatment of grippe and acute articular rheumatism, that it would be equally valuable in the treatment of infantile palsy.

As a salicylate it is surely of known germicidal value. As an ammonium salt it is stimulating and eliminates itself, in part, through the upper respiratory tract. It may be taken for one or two days, at least, without appreciable unpleasant effects, and it is unquestionably more indicated than any other drug I know of at present.

I hope to have it receive a wide trial and also to be compensated by knowing it has been useful. I trust my colleagues will let me know of any of their successes. To children it may be given dissolved in flavored water.

42 West Thirty-seventh Street.

News Items

Medico-Chirurgical Society of Central New York.—At the annual meeting of this society, held in Syracuse recently, the following officers were elected: President, Dr. Edward P. Hall, of Skaneateles; first vice-president, Dr. J. M. Keese, of Syracuse; second vice-president, Dr. L. S. Henry, of Syracuse; secretary and treasurer, Dr. E. A. Gayde, of Utica.

Doctor Darlington to Study Health of Army at the Mexican Border.—It is reported that Dr. Thomas Darlington, of New York, will be sent by the National Civic Federation to the Mexican border to study health conditions of the enlisted men of the army and the State militia. Special attention will be given to the causes of disease, to camp sanitation, and to food supplies. It is said that Secretary of War Baker approves of the plan.

Yellow Fever Commission Reaches South America.—The Yellow Fever Commission of the International Board of the Rockefeller Foundation, headed by Surgeon General William C. Gorgas, United States Army, arrived at Lima, Peru, on July 11th. The commission will study sanitary conditions at the port of Iquitos.

Prize for Infantile Paralysis Cure.—It is reported that Representative Isaac Siegel, of New York, has introduced into Congress a resolution appropriating $100,000 to be given as a reward to the person who succeeds in developing a cure for infantile paralysis. It is expected that the appropriation will be rushed through both houses.

Kentucky Valley Medical Association.—The following officers were elected at the annual meeting of the society, held in Richmond, Ky., on June 30th: Dr. Clarence H. Vaught, of Richmond, president; Dr. Wilson Bach, of Jackson, vice-president; Dr. J. H. Evans, of Beattyville, secretary and treasurer. Next year's meeting will be held in Jackson.

Cuba Quarantines Children.—According to cable despatches from Havana, the Cuban military authorities have adopted quarantine restrictions against United States children on account of the epidemic of infantile paralysis. In the future children arriving from American ports who have an abnormal temperature will be isolated until the trouble is diagnosed, while children in normal health will be kept under surveillance until the danger of infantile paralysis has passed.

New Britain Physicians Give Services to Country.—The New Britain, Conn., Medical Society, at a recent meeting, voted to give free medical attention to all persons who were in any way dependent upon the men who have gone to serve their country at the Mexican border. One of the local drug stores has offered to give free prescriptions to these persons also. The members of the society wish to emphasize the fact that this is not charity. It is the method they have adopted of aiding their country in the present crisis.

The Mayo Clinic to Establish a Base Hospital on the Mexican Border.—Colonel Jefferson R. Kean, Medical Corps, United States Army, who is director general of military relief of the American Red Cross Society, announces that a letter has been received from Dr. William J. Mayo, of Rochester, Minn., stating his willingness to organize a base hospital, the personnel and equipment of which are to be furnished by the Mayo Clinic. The number of medical officers in a base hospital is twenty-three, the number of beds 500, and the cost of the equipment is estimated at $25,000.

Connecticut State Health Officials Hold Annual Meeting.—The eighth annual convention of the health officers of the State of Connecticut was held in Middletown on June 30th. Dr. Edward K. Root, of Hartford, president of the Connecticut State Board of Health, presided. At the closing session steps were taken to perfect a permanent organization of the State health officials, and a resolution was adopted to that effect. The chairman was authorized to appoint a committee representative of the various health interests of the State, to prepare a constitution and bylaws and to call a meeting for purposes of organization.

American Association for the Study of Spondylotherapy.—The annual meeting of this association will be held in Chicago, September 18 to 21, 1916. An excellent program of papers will be presented, dealing with the latest advances in spondylotherapy, electronotherapy, reflex therapy, and physical therapy. All members of the medical profession are invited to attend. The officers of the association are: Dr. Albert Abrams, of San Francisco, honorary president; Dr. F. J. Bomberger, of Mapleton, Minn., president; Dr. William L. Heeve, of Brooklyn, N. Y., first vice-president; Dr. Valdemar Sillo, of New York, second vice-president; Dr. S. Edgar Bond, of Richmond, Ind., secretary-treasurer; executive committee, Dr. Edward J. Agnelly, of Detroit; Dr. Hugo Summa, of St. Louis, and Dr. J. W. Unger, of West Point, Miss. Dr. Bond will be glad to furnish full information regarding the meeting to all who are interested.

Base Hospitals for Massachusetts Troops.—Three base hospitals are to be established on the Mexican border for the benefit of Massachusetts troops. These institutions will be conducted by units drawn from the staffs of the Massachusetts General Hospital, the Boston City Hospital, and the Peter Bent Brigham Hospital. A fund of $25,000 is being collected for the support of this service.

Pacific Coast Oto-Ophthalmological Society.—At the recent annual meeting of the society, held in Portland, Ore., Dr. C. A. Veazie, of Spokane, was elected president; Dr. P. A. Jordan, of San José, Cal., first vice-president; Dr. Frank A. Burton, of San Diego, second vice-president; Dr. L. D. Greene, of San Francisco, secretary-treasurer. Next year's meeting will be held in Spokane.

A Special Meeting at the Academy on Infantile Paralysis.—On Thursday evening, July 13th, a special meeting was held at the New York Academy of Medicine for the purpose of discussing infantile paralysis. The following program was presented: What We Know About the Transmission of the Disease, by Dr. Simon Flexner; Clinical Types of the Disease, by Dr. Henry Koplik; Abortive and Nonparalytic Cases, Their Importance and Their Recognition, by Dr. George Draper; The Present Epidemic—the Types Which It Presents, by Dr. Louis C. Ager; Laboratory Aids in the Diagnosis, by Dr. Josephine B. Neal; Importance of the Present Epidemic, by Dr. Haven Emerson. A general discussion followed.

Sites for New Tuberculosis Hospitals.—A site has been selected for a new and larger county tuberculosis hospital in Broome County, N. Y., to take the place of the present institution, which is not only inadequate but is in an unsuitable location. The new site, which is near Chenango Bridge, has been informally approved by the State Department of Health. In Niagara County, a site has been selected by the Board of Supervisors about a mile and a half from Lockport, for the new hospital for which $100,000 was made available recently. Supervisors' committees in Herkimer, Rockland, and Nassau Counties are looking for sites for their county tuberculosis hospitals, and in each county several suitable properties are under consideration.

The First Hay Fever Ordinance.—A recent number of the *Weekly Bulletin* of the Department of Health of the City of New York, commented on the assertion that New Orleans was the first American city to adopt a hay fever ordinance providing for the cutting of weeds. It was pointed out that the board of health of the New York department adopted such a law at least six months previously. The department states that it is now in receipt of a letter from the health authorities of Savannah, Ga., calling attention to an ordinance providing for the removal of weeds and other vegetable growth, originally passed by the city of Savannah on August 28, 1900. This law was subsequently amended and in its present form dates from July 3, 1910.

The Infantile Paralysis Epidemic.—On Monday, July 10th, 103 new cases, with 14 deaths, were reported in greater New York, and on Tuesday there were 195 new cases, 115 in Brooklyn, with 32 deaths. Since the outbreak of the epidemic there has been a total of 1,278 cases, with 270 deaths. Everything known to science is being done by the health authorities to curb the spread of the disease. On Wednesday morning, Mayor Mitchel called a conference of the heads of city departments, the medical advisory board of the health department, and a number of prominent physicians, among them being Dr. Simon Flexner, Dr. L. Emmet Holt, Dr. William B. James, Dr. H. M. Biggs, Dr. William M. Polk, Dr. A. H. Doty, Dr. J. Winters Brannan, Dr. Abraham Jacobi, Dr. Walter B. James, Dr. Francis C. Wood, and Dr. Glentworth R. Butler. Congress has been asked to appropriate $135,000 to be used by the United States Public Health Service in fighting the epidemic in New York and to prevent its spread to other States. The Public Health Service reports that while cases of the disease have been reported from various parts of the country it is epidemic in New York city only.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Twenty-eighth Communication.

PHOSPHORUS.

Phosphorus is an irritant poison exerting a peculiar effect on parenchymatous and osteoblastic tissue. Although reports from different observers are not always in accord, the following sequence of processes seems usual. The irritation of phosphorus initiates a primary hyperemia of the cells of the alimentary tract, liver, and kidney; this is accompanied by a remarkable acceleration of the intracellular metabolic processes wherein the catalytic changes soon greatly exceed the anabolic; imperfectly metamorphosed products of the cells are thereby thrown into the circulation and the cells become infiltrated with minute fat globules from the blood stream. These fat globules soon coalesce and, with continuance of the endosmotic current of fat there ensues an intracellular pressure which rapidly lowers the vitality of the cells, resulting in necrosis and death. Following destruction of the epithelial cells, the structures beneath set up a protective growth of fibrous connective tissue, but this ultimately defeats tissue conservation by terminating in a static cirrhosis.

In some respects the action of phosphorus on bone is similar in the early stages, though without causing fatty infiltration. There is a stage of hyperemia and increased activity of the osteoblasts which results in a partial or complete substitution of cancellous tissue with dense compact bone, the medullary canal becoming larger and the bone harder and denser. But with the absorption of the cancellous tissue the actual strength of the bone is diminished, as since this cancellous tissue is of great service in distributing lines of stress, the bone also has its tensile strength lessened directly by a lowering of vitality, so that a condition akin to rickets frequently arises in cases of chronic poisoning.

Naturally such a hyperemia of the marrow of long bones must result in a stimulation of the blood forming tissue, with increase in the number of red blood corpuscles. Continuance of the drug irritation brings on a degeneration of the marrow, with serious interruption of corpuscle formation.

On other tissues of the body phosphorus seems to have little effect. The central nervous system shows practically no change, there is no observable effect on respiration or blood pressure, and the heart is not affected except by toxic doses, although in chronic poisoning the heart muscle, together with the muscle system as a whole, partakes in the general tendency to undergo fatty infiltration.

The alimentary tract suffers early and severely through fatty infiltration of the epithelial cells and the sequent intercellular fibrosis. Bile salts are decreased; bile pigments are increased at first, but later decreased; the glycogen and lecithin are also reduced.

From all these considerations we may be led to conclude that the one certain indication today for the use of phosphorus is disturbances of bone development. The local increase in blood supply, and the seemingly specific irritation of the osteoblasts, frequently induce such a stimulation of osteogenesis as to measurably compensate for previous deficiencies. The pill of phosphorus is the best preparation, each pill containing 0.6 mgm.

Management of Cases of Delay in Breech Presentation Due to Extension of the Legs.—Robert Jardine (*Glasgow Medical Journal,* February, 1916) points out that cases of this type are not, strictly speaking, instances of impaction. The explanation commonly vouchsafed for the delay in descent, viz., that the extended legs, lying along the child's body well up on the chest, act as splints and prevent the lateral flexion of the body supposedly necessary, is held invalid by the author, who shows that this lateral flexion occurs only at the outlet and has no bearing on the descent when the child is still above this level. From prolonged observation he is convinced that, instead, the breech is prevented from descending by the retraction ring. The membranes in these cases have always ruptured very early in or even before labor, and before the os has been fully dilated the retraction ring grips firmly the child's body either behind the knees or just below the feet, contracting with each uterine contraction and thereby preventing progress. Often a sulcus can be felt or seen running across the abdomen between the umbilicus and pubes, but the retraction ring can be detected much earlier by passing the flattened hand beyond the presenting part, when it will be felt as a distinct ledge running around the interior of the uterus and gripping the child. In breech cases the hand should be passed up over the front of the child under deep anesthesia, and extension of the legs will then be recognized. In this event, if the os is not fully dilated, dilatation should be completed manually and the child promptly delivered, preferably by passing up a hand, swinging one of the child's legs inward, and bringing it down below the retraction ring. Traction should then be made upon it to bring the body down, an assistant meanwhile firmly compressing the uterine fundus to keep the head well flexed and arms down—else they will probably be caught by the ring and the child's life perhaps be lost in consequence. Delivery should be completed in the usual way, by firm suprapubic pressure combined with gentle traction on the body. As a rule this will not interfere with the third stage of labor. Opium and deep anesthesia are alike powerless to relax the retraction ring when once it has formed.

A Suction Bougie for Chronic Gonorrhea.—A. Cambell (*Brit. Med. Jour.,* June 10, 1916) describes a bougie consisting of a flexible wire tube, wound spirally, with the coils close together. In use this is thoroughly lubricated, slipped over a suitable sound, introduced into the urethra and the sound is then removed, leaving two inches of the bougie projecting from the meatus. Over this free end is slipped a hollow metal cover, one end of which has a conical tip to fit closely into the meatus. To the other end there is attached the tube leading to a small drainage chamber which is connected to a mercury manometer on the one hand and a suction pump on the other. With everything in place, suction is slowly begun and increased almost to one atmosphere of minus pressure. This suction is maintained for fifteen to twenty minutes and is then slowly reduced. On removing the catheter many small masses of yellowish purulent material will be found in the crevices between the coils of the wire. These are removed from the pockets lining the urethra and often contain gonococci, even when previous examination of the prostate and urethra does not show any organisms. Following the use of suction the urethra is irrigated with a one in 4,000 to one in 8,000 solution of potassium permanganate. This form of treatment has proved successful in chronic cases and has given prompt results where other measures had completely failed.

Cartilage Transplantation in Plastic Surgery.—H. Morestin (*Bulletin de l'Académie de médecine,* May 23, 1916) attributes to cartilage transplantation an important role in plastic surgery, especially in mutilating wounds of the face and cranium. Transplanted cartilage is not only well borne, but becomes actually engrafted locally and persists without reduction in size or other particular change. It is easily cut and extemporaneously modeled by the surgeon. Material is obtained with impunity from the costal cartilages, especially the sixth, seventh, and eighth, and transplants from another individual may be used, if desired. Cartilage transplantation affords a simple, certain, and very precise means of repairing losses in the cranial bones. Through the already existing scars missing portions of bone are completely replaced by variously fashioned cartilaginous fragments, which require no support other than is afforded by bringing together the superficial soft tissues. The perichondrium, where preserved, should be placed inward, as there is a tendency to incurving on this side. No drainage is required. The method is distinctly superior to all others in making good depressions at the lower part of the forehead and for restoring the upper orbital margin. The lower and outer margin of the orbit and the malar prominence, hitherto offering an insoluble plastic problem, can also be confidently restored; in this way preliminary operations for closing sinuses and restoring the conjunctival sac and eyelids being, however, frequently required. Even the superior maxilla may be restored with cartilage. In ophthalmic plastic work, the orbital cavity may be in part filled with blocks of cartilage, thus preventing the sinking in of artificial eyeballs to too great a depth and favoring proper symmetry of the natural and artificial eyes. Loose pseudarthroses and extensive bony losses of the lower jaw are also susceptible to marked amelioration by the insertion of cartilage, though the propinquity of the septic oral cavity and the movements of the jaw represent difficulties to be surmounted. By transplanting the sixth, seventh, and eighth costal cartilages in one piece, the whole ascending ramus and much of the horizontal arch of the jaw can be reconstituted. Many other applications of cartilage transplantation are possible, as in joint surgery the reconstitution of the bones of the forearm, the metacarpals, the phalanges, and the repair of all other osseous deficiencies in which light skeletal support is alone required. Most of the author's cartilage transplantations were done under local anesthesia.

Treatment of Pruritus ani.—Charles J. Drueck (*International Journal of Surgery,* June, 1916) finds it essential to treat the cause, if possible. At times, a few inverted hairs may give rise to this condition. The diet should be regulated; no excess of meat, spices, condiments, sugars, etc., should be permitted. If constipation is present, the bowels should be emptied thoroughly with a saline or rhubarb. Aloin is contraindicated because of the irritating effect on the rectum. The genitourinary system should be examined for anything that may give rise to a reflex irritation. If syphilis is the cause, mercury and the iodides should be employed. If due to lithemia, salicylates and alkalies should be given. Linen should be worn next to the skin rather than wool. Pajamas should not be worn, as they fit too closely. Locally cleanliness and keeping the parts dry must be required. Autogenous vaccines have been used with success in some cases; the x rays have proved useful in others.

Chancroidal Adenitis.—H. Gougerot (*Paris médical,* May 6, 1916) notes that inguinal adenitis, in the absence of lesions of the lower extremities or abdomen, may be of three types: 1. Acute or subacute suppurative adenitis occurring in association with an active or recently healed genital lesion; 2, subacute suppurative adenitis without portal of entry; 3, chronic suppurative adenitis persisting months after a chancre. Adenitis of the first type is usually due to chancroidal infection. In most instances the primary chancroidal lesions coexist and are readily discovered, but in some they are already healed; a month or more may elapse between the healing of the soft chancre and the appearance of adenitis. While all suppurative adenitides of venereal origin should be suspected to be of the chancroidal form, coexisting syphilis should always be thought of, even in the presence of a most typical chancroidal lesion. The second type of adenitis is due sometimes to streptococci or staphylococci which have gained entrance through the urethral or the anal mucosa, at other times to the chancroidal organism, constituting thus a chancroidal adenitis without a chancroid. The author reports two cases of the latter form. Recognition of this subacute variety is of practical significance, for untreated the condition may drag on for a long time, may ulcerate, and may even terminate in phagedena. Truly chronic venereal suppurative adenitis is exceptional. One of Gougerot's cases had a chancroidal phage-

dena for five years, eventually succumbing to typhoid fever. Cases of chronic chancroidal adenitis with sinus formation may be associated with local tuberculous involvement and may lead to a condition of the surrounding skin resembling elephantiasis. On the whole, the marked clinical variations in chancroidal buboes must be clearly borne in mind. The treatment of inflamed but not yet softened inguinal glands consists of rest in bed, mercurial or silver applications to the chancroids, and gray oil or collargol ointment applications to the glands themselves. Calomel ointment or masses of cacao butter containing 0.03 or 0.04 gram of gray ointment may be applied to the chancroids. This procedure failing, hot moist dressings should be used and the bubo punctured, when pus has collected, at a point where the skin is still fairly resistant; the pus should then be evacuated, iodoform and ether injected, these evacuated, and the procedure repeated until the ether returns clear, when some of it is allowed to remain in the cavity, the needle is withdrawn, and a cotton dressing applied. Where sinuses exist, iodoform and ether or zinc chloride should be used. For chronic ulcerations, with or without phagedena, tissue destruction with hot air at 700° C. under general anesthesia should be tried. Avoidance of sinus formation, through treatment of early cases by puncture and not by incision, should be the chief aim.

Orthopedic Treatment in Old Hemiplegia.—George R. Elliott and Samuel W. Boorstein (*Jour. A. M. A.*, July 1, 1916) give in full the case history and details of treatment employed for a patient who had a complete hemiplegia for twenty-five years. As a result of various orthopedic measures he was soon enabled to walk well and to regain a moderate degree of use of his paralyzed arm. The striking results of treatment in this long standing case of paralysis and contracture serve to emphasize the need for a revision of our ideas of prognosis in hemiplegia and the need for prompt and adequate orthopedic treatment in all cases, beginning as soon as consciousness is thoroughly restored.

Hypertonic Solutions and Mineral Oil in the Treatment of Infected Wounds.—A. Goubaroff (*Presse médicale*, May 25, 1916) recommends the following measures, which, in his experience, have yielded the best results in cases of infected wounds: After the skin has been painted with tincture of iodine the wound is thoroughly opened up and foreign bodies are removed directly with forceps or by irrigation with isotonic salt solution or Dakin's hypochlorite solution. Occasionally, in malodorous wounds with gangrenous tissues still adherent, heated air at 300° C. is applied; usually, however, such wounds are merely irrigated with a hypertonic, eight to ten per cent. solution of sodium chloride. This type of solution is well borne, causing no irritation or pain, exerting a pronounced hemostatic action, and having marked antiseptic and deodorant properties. It draws lymph freely into the wound, thereby affording a favorable field for phagocytosis. Large rubber drains are introduced and the wound is then filled with dry sterile gauze previously dipped in liquid petrolatum. Where there is marked fetor, or in penetrating mouth wounds, the gauze is impregnated with hypertonic salt solution instead. At times even tablets of salt are introduced between the layers of gauze. In most instances, change of dressing consists simply in introducing a little liquid petrolatum into the wound. The surrounding skin is cleansed with cotton dipped in benzine or gasoline. The oily dressing never adheres, traumatism, pain, and bleeding when it is removed being therefore obviated. Another procedure which gives excellent results in these wounds is exposure to direct sunlight, or, as recommended by Chaput, to electric light.

Postoperative Ileus.—William M. Thompson (*Surgery, Gynecology, and Obstetrics*, June, 1916) arrives at the following conclusions: First, that the best results in the treatment of inflammatory ileus are obtained by enterostomy and drainage in cases so severe that radical measures would be fatal. Enterostomy should be done rapidly and without disturbing adhesions. When the patient recovers ileoileal anastomotic closure of the enterostomy wound and cecostomy or appendicostomy will complete the cure; second, that in favorable cases ileoileal anastomosis with cecostomy or appendicostomy for drainage and to relieve back pressure in the colon gives the best results; third, that by short circuiting and putting the damaged gut at rest it may be restored to health and function even after vascular changes have taken place; fourth, that the mortality of resection for this disease is too high to give it a place in the treatment of inflammatory ileus; fifth, that the adhesions should not be broken up nor the damaged gut handled in the operation.

Paraffin for Lousiness.—B. Hall (*Brit. Med. Jour.*, June 10, 1916) has found that the following is a simple and effective means of curing this condition: With the exception of the scrotum the entire body of the victim should be wetted with paraffin oil, which the patient may apply with his hands; the application should be made without rubbing, since that would cause a dermatitis; when wetted all over, the back having been done by an orderly, the patient should dress at once. A single application is invariably successful.

Treatment of Malarial Hemoglobinuria.—K. Ross (*Jour. Florida Med. Assn.*, June, 1916) finds that nephritis is present in all cases and influences the treatment. Elimination through the skin and bowels should be secured and the kidneys should be rested. Repeated doses of twenty to thirty grains of calomel should be given every two hours until from sixty to 120 grains have been taken. One eighth to one quarter of a grain of pilocarpine hydrochloride should be administered every four hours to promote sweating and should be continued so long as the hemoglobinuria persists. For the nervousness, doses of twenty to thirty grains of sodium bromide may be given every three or four hours. Since morphine inhibits elimination, it should not be used and quinine must not be used at all on account of its hemolytic properties. Alcohol is also absolutely contraindicated. Stimulation, in the form of small doses of digitalis is usually needed during the attack, and nitroglycerin, strychnine or digitalin may be given hypodermically when immediate stim-

ulation is demanded. The aftertreatment consists of rest, tonics and change of residence to a nonmalarial region.

The Effect of Ferrivine and Intramine on Syphilis.—By employing several cases of well marked secondary syphilis with pronounced lesions, L. W. Harrison and C. H. Mills (*Lancet*, June 17, 1916) tested the value of these two new compounds recently brought forth by McDonagh. No beneficial effects whatever were produced and the syphilitic lesions even increased in one case during treatment. The same lack of results was observed in a case of gummatous lesions. Aside from being devoid of therapeutic action, ferrivine caused very intense and even threatening constitutional reactions every time it was given, while intramine often led to local tissue necrosis and abscesses. The injection of the latter drug was also followed by intense local pain lasting several days. The subsequent use of salvarsan in the same cases gave prompt results.

Craniocerebral Wounds of War. — Harvey Cushing (*Military Surgeon*, June, 1916) states that there is no unanimity of opinion as to what should be the routine treatment of cranial wounds at first line hospitals. Some surgeons owing to sorry experience advocate leaving all except the minor injuries alone; some advise immediate trepanation only of the tangential wounds in which the dura presumably has escaped injury; but by far the larger number, basing their views on the experiences of earlier wars, recommend the prompt treatment of every case at the earliest moment. The usual operation consists in enlarging the wound with a crucial incision, elevation of depressed fragments, the removal as far as possible of the spicules driven into the brain, and direct drainage usually with an iodoform gauze pack.

Suppurative Otitis media.—E. Hamilton White (*Canadian Medical Association Journal*, June, 1916) urges that at the onset of an acute suppurative otitis strict confinement to bed should be insisted on until it is established that the infection is mild, and that the disease is running a favorable course, and that a limit should be put to the time during which such an ear shall be allowed to discharge by thorough investigation as to the cause of delayed healing, and by the adoption of active surgical measures in appropriate cases. Every week of added discharge makes it more certain that the hearing will be damaged permanently and brings nearer the danger of serious deep seated trouble.

Resuscitation Apparatus.—Yandell Henderson (*Jour. A. M. A.*, July 1, 1916) notes several ingenious pieces of apparatus for use in resuscitating drowned, asphyxiated, or poisoned persons who are suffering from failure of respiration. The various apparatus have been examined by the author and the most that can be said of the best of them is that they provide mechanical means of artificially supplying air, or air slightly enriched with oxygen, to the lungs. Perhaps the greatest danger from their use lies in the fact that too much reliance is placed upon their efficiency and thus too often the victim is neglected while the apparatus is being brought. For resuscitation the most important element is prompt action and there should be universal training in the technic of the prone pressure manual method of artificial respiration. Where available immediately most of the forms of apparatus are capable of giving good results, since they give fuller ventilation of the lungs than is possible by the manual method. In gas and smoke cases oxygen should be administered at once and the only effectual method for this is by means of a closely fitting face mask and a distensible rubber bag.

Causes and Treatment of Perthes's Disease.—Frederick C. Kidner (*American Journal of Orthopedic Surgery*, June, 1916) relates a case operated in for osteochondritis deformans juvenilis which presented symptoms almost typical. He found beneath the epiphyseal line of the femur a walled off cavity containing a soft grayish red material which, on examination, showed a growth of Staphylococcus aureus of low vitality. From the study of this case the author considers that the disease is due to a low grade hematogenous infection and that operation, followed by mechanical treatment, is indicated.

Urethroplasty at the Base of the Glans penis.—Courtney W. Shropshire and Charles Watterson (*Annals of Surgery*, June, 1916) state that in doing this work the following points should be observed: First, the urethral tract must be free from disease; second, control oozing as much as possible with hot packs; third, place all sutures with lower part of the U parallel with long axis of penis; fourth, do not tie the sutures too tightly; fifth, wash the bladder through a catheter with saturated solution of boric acid daily; sixth, remove the catheter every other day and irrigate the urethra without distention, with solution of boric acid, but do not use a mushroom catheter; seventh, dress the wound by painting it with tincture of iodine, three per cent., on the third day, remove catheter on the seventh day, and have patient drink a half gallon of water daily, beginning as soon after the operation as possible. Take out the first sutures on the fourth day and remove the retention suture, last, on the tenth day.

Subastragalar Arthrodesis in Lateral Deformities of Paralytic Feet.—DeForest P. Willard (*American Journal of Orthopedic Surgery*, June, 1916) states that the operation devised by Dr. G. G. Davis for correction of the lateral deformities of paralytic feet consists of two incisions on either side of the foot below the malleoli, drawing aside the tendons and then digging up or gouging out the surfaces of the joints of the astragalus and scaphoid and os calcis. The author asserts that the operation insures a more stable foot, does away with the use of braces and does not prohibit other operation. No recurrences have followed this operation.

Foreign Bodies in the Respiratory Tract.—Nathan W. Green and Leon T. LeWald (*Annals of Surgery*, June, 1916) draw the following conclusions: 1. All recently aspirated foreign bodies should first be sought by the Röntgen ray and the bronchoscope without delay, and removed if possible through the mouth. 2. If they cannot be removed

through the mouth, tracheotomy should be done and another attempt made by means of the bronchoscope. 3. Failing in this the tracheal wound should be held widely open by wires or by a large tube in the hope that the foreign body may be coughed out. 4. If immediate removal by these methods is unsuccessful, a period generally elapses during which patients may undergo secondary changes in the lung, such as pneumonia, gangrene, abscess, and generally an overlying empyema. 5. If patients recover from these acute infectious processes, they pass into the class of deferred cases with the foreign body still present as an aggravating factor in their chronic lesion. 6. Removal of the foreign body in these deferred cases does not always effect a cure. 7. Lung abscesses must be treated along surgical lines, and even then we cannot always hope for cure, but only amelioration of the affliction.

Twilight Sleep.—Charles B. Reed (*Surgery, Gynecology and Obstetrics,* June, 1916) considers that from case observation the morphine scopolamine analgesia when properly administered is harmless both to mother and child. The treatment has been successful in these cases, since twenty-nine per cent. of the cases were practically and fifty-six per cent. entirely free from pain—or eighty-five per cent. in all. Strength is conserved and the convalescent period is shortened. Whether or not the woman gets up earlier is a question of uterine involution rather than one of days, or of strength or of treatment. The important consideration is that she feels better much sooner. Primary pain, weakness, hemorrhage, prolapsed cord, and a lack of correlation between the size of the pelvis and the child, are conditions unfavorable to "twilight sleep." Twilight sleep will not succeed in every case, but does no harm when properly used and it will act happily in about eighty-five per cent. of the cases selected with due regard to contraindications.

Colloid Gold in the Treatment of Pneumonia.—Commes, at a recent meeting of the Société de pathologie exotique (*Presse médicale,* May 25, 1916), advised intravenous injections of colloid gold, begun as soon as the diagnosis is established, in pneumonia. One to two c. c. of the remedy may be injected without untoward result. Three daily injections are generally sufficient to cause a return of the temperature to normal and to arrest the progress of the disease.

Desiccation in Ophthalmology.—William L. Clark (*Jour. A. M. A.,* July 1, 1916) finds that heat of just sufficient degree to desiccate, but not to carbonize the tissues is of great value in the treatment of new growths and congenital tumors about the eye. Such heat can be most satisfactorily produced from a high speed static machine fitted with a suitable transformer, and can be best applied through the medium of a fine steel needle which is lightly brushed over the growth. The part to be treated should first be anesthetized locally with cocaine or novocaine. From an extensive use of this form of treatment the author draws the following conclusions: That it is a successful method of treatment for localized basal cell epitheliomas about the eye, for it has cured the majority of cases in which it has been properly applied. Where there have been recurrences a second or third application has usually relieved the condition. The cosmetic results are excellent. In advanced cases complete cure is not certain, but much temporary relief may often be given. Round cell sarcomas and melanosarcomas have also responded favorably, and success is certain in such benign growths as angiomas, warts, xanthoma and lupus erythematosus. It is also of value in the treatment of granular conjunctivitis and ulcers of the cornea.

Treatment of Typhus.—R. O. Moon (*Lancet,* June 10, 1916) asserts that thorough ventilation is the most important factor, not only as an antipyretic but as a nerve sedative, tending to lessen the violent headache and insomnia of the early stages. Hydrotherapy is valuable employed in the form of cold baths, cold local applications or the water mattress which should not be below 65° to 70° F. Where cold baths cannot be given, morphine is of great service hypodermically for headache, delirium and insomnia. The diet should be mainly milk until the temperature reaches normal.

Intraperitoneal Inoculation of Animals: Its Diagnostic Value in Orthopedic Surgery.—Melvin S. Henderson (*American Journal of Orthopedic Surgery,* June, 1916) reports that in a series of 143 cases of suspected tuberculosis forty were reported as positive by the inoculation test. Joint fluids, purulent discharges and emulsified tissues were injected into the peritoneum of guineapigs. In children, when tests were made, injection into rabbits was used in addition as a check. The writer considers the test practicable and of especial value in obscure cases where a positive result serves to determine the diagnosis. He performs the test three times before giving a negative diagnosis.

Behavior of Hypochlorites on Intravenous Injection.—H. D. Dakin (*Brit. Med. Jour.,* June 17, 1916) observes that eusol has been recommended for intravenous injection in man. Granting that the maximum possible concentration of the hypochlorous acid contained in the full dose persisted for a short period of time, there would only be from fifty to sixty-five mg. of the acid present per litre of blood. This is far below that concentration which shows any active direct action on such organisms as the colon bacillus or staphylococci suspended in blood or serum *in vitro.* The action of the hypochlorites depends upon the active chlorine liberated and experiments, both *in vitro* and *in vivo,* have shown that the chlorine at once becomes anchored in an inert form to one or more constituents of the blood and that a very large quantity of hypochlorous acid has to be introduced to give the faintest detectable trace of active chlorine. Further, the idea of some secondary effect, such as the stimulation of antibacterial or antitoxic substances, is not supported by experimental results. Lastly the drugs of this group are not without harmful effects and even in small amounts produce hemolysis of the red cells in the living animal. The only conclusion which may be drawn from the experiments is that these substances, when injected intravenously in the doses advised, cannot have any appreciable direct germicidal action.

Miscellany from Home and Foreign Journals

Origin of Hypernephroma.—Alexander Fraser (*Surgery, Gynecology, and Obstetrics,* June, 1916) discusses the origin of hypernephroma and concludes: 1. Of thirty-four so called hypernephromata, there is convincing evidence, both clinical and morphological, that one of the number was a neoplasm originating in an accessory nest of cortical adrenal cells, although the possibility of origin from the cortical cells of a misplaced adrenal composite cannot, of course, be denied. It is interesting to note that the patient in whom this tumor was found was a female with pronounced male characteristics. In another case of so called hypernephroma, the tumor apparently rose from multiple nests of adrenal cortical cells lying in or around the capsule of the kidney. In the remaining thirty-two instances of so called hypernephromata, the tumors evidently were derived from renal adenomata. In other words, it would appear that the majority of cases of hypernephromata is misnamed, and should be classified as nephromata, the term hypernephroma being reserved for malignant tumors arising from cortical adrenal cells. 2. It has been shown, a, that the primary structure of tumors of adrenal origin is essentially different from the primary structure of tumors of renal origin; b, that the primary structure of adrenal tumors never imitates the primary structure of renal tumors; c, the primary structure of some renal tumors (adenomata) can, at an early stage, through proliferative changes, imitate the primary structure of tumors of renal origin; d, both tumors of adrenal and of renal origin can undergo secondary degenerative and malignant changes, which make their histological features similar, these changes being practically always present in the renal tumors. On the other hand, they occurred in only one of the two cases of adrenal growths described, consequently Fraser believes that the diagnosis of hypernephroma should not be based on the appearances presented by those parts of the tumor in which secondary degenerative and malignant changes have occurred.

Mild Forms of Typhoid Fever.—Roger Voisin (*Paris médical,* May 13, 1916), among 103 cases of typhoid fever in subjects not previously inoculated against the disease, met with forty-four mild cases of various types. One of these types was characterized by an abbreviated course of the disease, which lasted only from seven to thirteen days, in spite of the positive Widal reaction; a temperature of 39° C. was rarely exceeded in these cases, and the general condition remained good, the patient having one or two stools a day, with headache, malaise, a few rose spots, coated tongue, and distinct splenic enlargement. To such cases the term "typhoidette" is applied. A second, more frequent variety, comprising seventeen cases, was characterized by a rapid recession of the disease, frequently in spite of severe early symptoms, such as high fever, stupor, prostration, dry tongue, and pronounced diarrhea; the men affected persisted in their military tasks until the symptoms became very marked, but upon admission to a hospital these symptoms passed off usually in four to six days. A third type was that of gastric disturbance, with a fever of 38° C. or 38.5° C., initial vomiting and diarrhea, and a broad, coated tongue; purgation and a diet of water and later milk brought relief in four to eight days, but the enlarged spleen indicated a more profound systemic infection than the general condition suggested. The fourth type was of especial interest, essentially a typhoid enterocolitis, characterized by marked apathy and cephalalgia, a white tongue, malodorous breath, tenderness over the scaphoid, at times rigid abdomen, obstinate constipation, and a long drawn out course, the affection dragging on for several weeks, with a temperature seldom exceeding 37.5° C. and sometimes persistently normal in spite of the accompanying symptoms. The fifth type showed successive recrudescences of fever, sometimes separated by intervals of apyrexia, with reappearance of rose spots at each recrudescence, but presenting symptoms, in general, rather mild. In none of these five forms were any complications noted, although previous experience had shown that hemorrhage and perforation might occur even in mild typhoid cases.

Grippe in Nurslings.—R. Raimondi (*Presse médicale,* May 11, 1916) observes that at the end of October, in November, and in December, grippe in nurslings is relatively mild, lasting as a rule only from three to five days. In the second week of January, however, severity increases, and the disease is regularly most virulent from March until the beginning of May. When infants are in unhygienic surroundings the affection is promptly acquired and the incubation period, generally forty-eight hours, is reduced in many cases to twelve or twenty-four hours. During some months the tracheal form of grippe, with otitis, may be most common, while during others the bronchial form with lung complications will predominate. In some instances nervous symptoms such as extreme prostration and somnolence, or insomnia, are most conspicuous; or, gastric, gastrointestinal, and especially hepatic involvement may attract attention. The liver should always be percussed and palpated in the infant with grippe, as it is often congested, tender, and enlarged, especially on the left side. High degrees of fever occur particularly when the liver or other alimentary organ is involved. The beginning of convalescence is marked by a temperature lower than 37.5° C., both morning and evening, for a period of four days; whenever these conditions are not fulfilled, a return of high fever may occur and the grippal infection has not yet been mastered. Grippe is differentiated from measles by more pronounced temperature oscillations in the former and by less pronounced lacrymation. The cough of grippal tracheitis differs from that of whooping cough in being accompanied by fever and is more persistent and exhausting. The symptoms of catarrh of the mucous membranes preceding the in-

testinal involvement of grippe differentiates it from enteritis due to dietetic error. An enlarged liver, without splenic enlargement or jaundice, but with catarrh of the respiratory mucosæ, indicates hepatic grippe. Redness of the tonsils and pharynx frequently accompanies the grippal coryza of infants. In all weak infants the probability of pulmonary complications of grippe renders the prognosis sombre.

Acute Perforation of Ulcers of the Stomach and Duodenum, with Case Reports.—Martin T. Field (*Boston Medical and Surgical Journal,* June 8, 1916) observes that acute perforation of gastric and duodenal ulcers is not an uncommon accident. Early operation yields a high percentage of cures, while late operation gives a low percentage. It occurs most often in adult males who give a history of stomach trouble. Its possibility is not excluded by complete absence of dyspepsia. The most important diagnostic guide is a sudden, severe epigastric pain, followed immediately by signs of a spreading peritonitis, which manifests itself through general tenderness and muscular rigidity. Early or first hour general tenderness and rigidity are important signs in differentiating acute perforation from appendicitis and other intraabdominal lesions. The first points of maximum tenderness and rigidity, especially in duodenal perforation, are on the right side above and below. Later the rigidity becomes boardlike over the whole abdomen. Tympany over the liver may occur, but usually is not present. The abdominal pain as a rule is very severe and patients have an anxious expression, but at first the pulse is often only slightly accelerated.

Facial Paralysis in Military Practice.—From clinical considerations the trunk of the facial nerve is held by E. J. Moure, in *Presse médicale,* April 13, 1916, to consist of two groups of fibres; the one comprising the superficial fibres is distributed to the muscles of the lower part of the face, the other including the fibres occupying the centre of the nerve is distributed to the upper aggregation of muscles supplied by the facial nerve. The first group thus forms a protective sheath around the second, and is more exposed to irritation and impaired function from external causes than is the second. In most patients with traumatic section of the facial nerve under Moure's observation, the involvement was only partial, the lower branches to the chin or lips being alone severed. Such patients were but little inconvenienced in speaking or even in masticating and required no special surgical treatment. Contusion or section of the upper branches, on the other hand, was often accompanied by fistula of Steno's duct and ophthalmic disturbances demanding surgical correction. The salivary fistulas were nearly always overcome by preventing mastication for three or four weeks. In relieving paralysis Moure was uniformly successful in three cases upon merely excising, under local anesthesia, all the thick cicatricial tissue intervening between the cut ends of the nerve fibres. The two margins of the incision were then sutured together, and within two or three months motility returned. Among six cases in which operation for removal of a missile from the mastoid process was instituted, the nerve was found actually cut in but one instance; in the others it was either compressed, lacerated, abraded, or neuritic, a large neuroma being found in one instance. The operative treatment in these cases consisted in broadening the bony channel in which the nerve is normally lodged and liberating it from above downward. The procedure is far more difficult than where the parts are changed in appearance by fungous granulations, pus, or osseous fragmentation, but the results in the author's cases were promising, paralysis completely disappearing in two cases and the condition being more or less improved in the remaining four.

Petroleum Ether in the Isolation of Typhoid Organisms from Stools.—H. C. Hall (*Berlin. klin. Woch.,* Dec. 27, 1915) describes a modification of Bierast's method, comprising the shaking out of the suspected stool with petroleum ether after emulsification in bouillon. Following the shaking out process the mixture is allowed to stand for about two hours at room temperature and a drop of the sediment is then plated out on Conradi-Drigalski plates and incubated for sixteen to twenty hours. This technic suffices to kill off practically all of the colon bacilli and to leave only typhoid and paratyphoid organisms. If the plates show practically pure cultures resembling those of either of these two types of organisms, the colonies from them can be emulsified and tested directly by agglutination to determine their precise nature. The modified method gives definite results even in doubtful cases in twenty-four hours, which is a great saving in time over previous methods. Experiments were made with several samples of petroleum ether and it was found that the ethers with higher boiling points were less actively destructive to colon bacilli, the most active of all being that ether which boils at about 50° C. The paraffins were also found to have some destructive action on Bacillus coli, especially pentane, which boils at 38° C.

Cardiac Palpitation Due to Arterial Hypertension.—Camille Lian (*Presse médicale,* May 22, 1916) calls attention to cases of this type met in military practice, referring in particular to the necessity of not mistaking them for instances of mere neurotic disturbance. Twelve cases were met in a single batallion of territorial infantry. The palpitation is usually manifest in tachycardia alone, with dyspnea and precordial oppression or pain, but may show an extrasystolic arrhythmia in addition. In light cases the disturbance appears on marching and passes off with rest, but in many others is permanent, persisting in recumbency, with a pulse rate often of 100 and in cases of intermediate severity never descending below eighty. Diagnostic investigations in these cases should be such as to detect any latent nephritis. The urine should be examined, and minor signs of uremia, gallop rhythm, and abnormal sharpness of the second aortic sound should be looked for. Blood pressure estimations are essential in the diagnosis. The systolic pressure will be found to be ten to fifty, and the diastolic pressure ten to twenty mm. above normal.

The heart in these cases has difficulty in performing the excess of work required by the high pressure, and the tachycardia is a symptom of left ventricular weakness. Tachycardia of neurotic or Basedow origin is distinguished by the relatively lower degree of hypertension. The patient should be relieved from military service if the excess of systolic pressure to forty or fifty mm. and that of diastolic pressure twenty mm.; if the pulse rate fails to recede below 100 at rest; or if arrhythmia is present. In the milder cases, the subject may be detailed for auxiliary service, or else receive relatively sedentary employment in his regiment and be relieved of arduous duties as well as of his knapsack in long marches. When the disturbance recurs, he may be placed at rest on a diet of vegetables and milk for a week or two.

Experimental Colonic Stasis.—Charles H. Frazier and Max Minor Peet (*Annals of Surgery*, June, 1916) conclude that the result of these experiments on colonic stasis would seem to indicate that mere stagnation of feces in the colon of the dog, when on a normal mixed diet, does not lead to the formation of toxic substances of note, at least, in the presence of normal flora of the canine colon. The fact that these dogs remained in perfect health and gained in weight would indicate that simple colonic stasis in a dog is harmless and certainly would suggest that the dire effects attributed to colonic stasis in man were, in part at least, due to some cause other than the absorption of products usually formed in simple fecal stagnation.

Diagnostic and Prognostic Significance of Disturbances of the Hairy Growth in Nerve Injuries.—Maurice Villaret (*Presse médicale*, May 18, 1916), from studies in over 165 cases, states that in a case of peripheral paralysis or contracture clearly due to a nerve lesion, if a diminution in the hairy covering is observed, the prognosis should be guarded, complete interruption of the nerve being indicated, whereas if hypertrichosis is noted an incomplete nerve lesion, such as lateral section, compression, or neuritis, is suggested. The indications for treatment vary in consequence. In clearly functional cases, a normal hairy covering suggests hysteria and exaggeration, and hypertrichosis, some vascular or sympathetic disturbance, or what Babinski terms reflex paralysis or contracture. The results of examining the state of the hairy covering coincide so frequently with those of electrodiagnosis that such examination can, to some extent, be substituted for electrodiagnosis, where apparatus for the latter is not available.

Dyspnea—Its Occurrence and Significance.—J. Wheeler Smith (*Medical Record*, June 17, 1916) divides dyspnea into two varieties—physicochemical and mechanical. The first variety is due to insufficient oxidation of the tissues independent of mechanical interference with respiration, while the latter is characteristic of mechanical dyspnea. Varieties of physicochemical dyspnea are that experienced at great altitudes, the dyspnea of anemia, of cardiac and renal disease, of pneumonia, and of tuberculosis. Mechanical dyspnea may be considered under two heads, that due to insufficiently pervious air passages and that due to inadequate respiratory movements. The former is called obstructive dyspnea and may be due to any obstruction which either narrows the lumen of the respiratory tubes or presses upon the tract from without. Smith reports a case of dyspnea in a man of forty-eight years due to tumor in the superior thoracic aperture. This was the result of great enlargement of the right group of tracheobronchial lymph glands whose primary focus was a small ulcerated epithelioma in the esophagus. The primary tumor was entirely overlooked because it was entirely without symptoms; both lungs were extensively involved; the severe symptoms were all due to the metastatic involvement of a small group of glands, so placed, however, in the rigid superior aperture as to be very important.

Functional Results after Excision of Large Joints in Military Practice.—Nové-Josserand and Tuffier (*Bulletin de l'Académie de médecine*, May 16, 1916), summarizing the results of 1810 joint resections, either primary, i. e., within three days after the injury, or secondary, to overcome suppuration, find that, in the upper extremity, 49.44 per cent. of favorable results were obtained, and in the lower extremity, 76.66 per cent. Primary resections were failures in eighty per cent. of the shoulder cases and in seventy per cent. of the elbow cases, as against only thirty-two per cent. of failures after secondary resections, whether of the shoulder or elbow. In the case of the hip joint, there was little difference between primary and secondary resection, while in the case of the knee primary resection gave good results, and secondary resection was frequently a failure. The mortality of joint resection was five per cent. in the upper extremity and twenty-seven per cent. in the lower. Joint resection, whether primary or secondary, is always to be preferred to amputation, which is justifiable only to save the patient's life.

Base Hospital Work in Russia.—H. H. Snively (*Military Surgeon*, June, 1916) comments upon the unusual freedom from epidemics among the civil population of Russia in the summer of 1915. The peasants said this was due to the absence of the doctors. Perhaps, the prohibition of vodka was a factor. This prohibition, while not absolute, is strict enough to be effective, and has had a tremendous value in the military way. There was so little drunkenness seen in the army or out of it that the sight of a drunken man was an unusual event, although no doubt officers and soldiers would have used liquor had it been obtainable. Among thousands of soldiers he saw only two cases of wood alcohol poisoning.

Sanitary Problems of Trench Warfare.—Lieut. Colonel Frank E. Keefer (*Military Surgeon*, June, 1916) says that we have as yet learned but little concerning improvements in military hygiene and sanitation, the difficulties in the practice of which have all been immensely enhanced by trench warfare. Rain and mud, frost and snow, filth, the problems of supply of food and water, the disposal of wastes, the prevalence of parasitic insects—all these and many more difficult problems press for solution or at least for amelioration. Men move to the trenches by stealth and at night. Unless the trench is completely "organized" as the expression goes, soldiers are never dry, or warm, or comfortable, during their entire tour of one or more days. They must take

with them their ammunition, food, and water, while those they relieve must carry out their own excreta. Frequently, those on duty stand in water and mud continually. They are tormented by some or all of a variety of insects, which may include flies, mosquitoes, lice, ticks, the itch mite, and bedbugs. The number of flies in Gallipoli is said to be "amazing." But as a matter of course the loathsome louse is the most pestiferous and distressing. Even when the louse is not the dreaded host of typhus, the insinuating attentions of this insect are hardly to be borne.

Trichinosis and the Cerebrospinal Fluid.—William Lintz in the *Journal A. M. A.* for June 10, 1916, reports three cases in which Trichina spiralis was found in the cerebrospinal fluid. The fluids appeared normal, contained no sediment, and only one of the three failed to reduce Benedict's solution. The centrifugated specimen showed a few lymphocytes and from one to four trichinæ in each field. Should the trichinæ be found in the cerebrospinal fluid with a fair degree of constancy it would be a quick method of making the diagnosis of trichinosis.

Examination of Normal Gastric Secretion by the Fractional Method.—Eugene S. Talbot, Jr., in the *Journal A. M. A.* for June 10, 1916, concludes as the result of work carried out on normal and pathological stomachs that the fractional method of gastric analysis should replace the old tube method. The true secretory curve of digestion can be determined only if the test meal is introduced into the empty stomach. The fasting stomach with this method gives a larger residuum than was formerly believed to be normal. The Ewald meal influences the intensity of appetite secretion variably in different patients. By the fractional method the high point of secretion and the rapidity of the change in acid secretion can be determined. No one form of secretory curve is common to all normal stomachs. The contour of a given normal curve depends on the intensity and duration of appetite secretion as influenced by the test meal, the amount of gastric mucus, the concentration of food secretion, and the emptying time of the stomach, which is fairly uniform.

Failure of Right Heart in Pulmonary Disease.—F. J. Poynton (*Lancet,* June 17, 1916) outlines briefly two cases of this secondary cardiac disturbance as the result of extensive, chronic pulmonary disease, and summarizes the more important symptoms and diagnostic features. Primarily there is a previous history of chronic and very extensive lesion of the lungs, which may be of any form, tuberculous or other. In such a case there will be an abrupt change from a pulmonary to a cardiac symptomatology with marked cyanosis and general lividity, and pronounced venous stasis. The jugulars will be engorged and phlebographs will often show an abnormally large A wave. Often the ventricular form of venous pulse will be wanting. The heart rate is usually rapid and the pulse small and feeble, but the rhythm is usually normal. The urinary output is not much diminished. The liver becomes greatly enlarged and tender and ascites and edema are usually marked. Auscultation reveals a tricuspid systolic murmur over the ensiform, and radiographs of the heart will complete the diagnosis by showing a greatly dilated right heart with a nearly normal left. When such a condition has developed in an old pulmonary case the prognosis is bad and treatment is of little avail. Digitalis may induce some improvement in the heart's action at first, but soon fails to be of any benefit.

The Etiology of Shell Shock.—Harold Wiltshire's (*Lancet,* June 17, 1916) critical study of the cases of shell shock leads him to conclude that wounded men are nearly immune from its development, the effects of the wound apparently antagonizing the psychic causes of the shock; that neither hardship nor exposure is a predisposing factor: that physical concussion is an exceedingly rare cause, as also is the chemical action of gases resulting from explosives. The two chief causes seem to be gradual psychic exhaustion from prolonged fear and some special psychic shock, such as that caused by a horrible sight. There is no necessary connection between sex complexes and the cause of shell shock.

Symptomatic Variations in Late Tetanus.—Léon Bérard and Auguste Lumière (*Bulletin de l'Académie de médecine,* May 16, 1916) found that in seven cases of late tetanus developing in subjects not previously immunized, the disease always appeared after secondary surgical procedures, at times very trifling, presented symptoms identical with those of early tetanus, and uniformly ended fatally, the systems of the patients having long been impregnated with septic products and toxins, and failing to resist the tetanic intoxication. Of fifteen cases in which tetanus followed supplementary surgical procedures in patients already immunized with one or more injections of tetanus antitoxin, the tetanus developing in from twenty-four to 122 days (average fifty-eight days) after the last preventive antitoxin injection, nine were cured. The symptoms in these cases were relatively mild, but grew more and more severe the longer the period between the preventive injections and the appearance of the disease.

Etiology of Iritis.—Ernest E. Irons and E. V. L. Brown in the *Journal A. M. A.* for June 10, 1916, note that of 100 cases there were only twenty-three in which syphilis was the cause of the iritis and sixteen others due to other causes in which syphilitic infection had occurred. In eighteen patients a dental lesion—either an alveolar abscess or an apical infection—was the source of the iritis. In sixteen cases the tonsil was the source of the infection. Gonorrhea accounted for nine cases—all in males. In eight of these cases an active or recent, usually multiple arthritis was present. Tuberculosis was the responsible factor in eight cases, sinus infection in three, and a nonvenereal infection of the genitourinary tract in three. Seventeen cases presented several infections, so that it was impossible to determine which caused the iritis. From the clinical study carried out by the authors it would appear that several factors are concerned in the production of iritis, among which may be noted the presence of a focus of infection partially protected from the resisting forces of the host, the periodical entrance into the blood stream of these organisms and their lodgment in the eye, changes in the eye itself, and, finally, changes in the organism itself.

Proceedings of National and Local Societies

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, May 16, 17, and 18, 1916.

The President, Dr. W. Stanton Gleason, of Newburgh, in the Chair.

(*Continued from page 94.*)

The Cerebrospinal Fluid in Cerebrospinal Syphilis.—Dr. Charles Clyde Sutter, of Rochester, analyzed the findings in fifty cases of cerebrospinal syphilis, including ten cases of general paresis and nine cases of tabetoparesis. He found the greatest value of the examination in paresis and tabetoparesis, next in cerebrospinal fluid, and lastly in tabes. The Nogouchi butyric acid seemed the most trustworthy of the globulin tests. It was present in almost all of the cases examined, forty-one out of fifty cases, and weak in four others. The cell count was a very important element in the study of the cerebrospinal fluid. When studied differentially it gave some insight into the severity of the meningeal reaction. The Lange colloidal gold chloride reaction was a useful adjuvant to the Wassermann and other tests. In paresis he found the typical paresis curve. In tabes dorsalis the reaction was not quite so characteristic and was present in a smaller proportion of cases. The chief advantages in this reaction were the small amount of fluid used, its technical simplicity, the sharpness of the reaction, and its delicacy. The reaction was particularly useful in differentiating incipient general paresis and neurasthenic conditions in the syphilitic. The positive Wassermann reaction was now a more constant finding in the cerebrospinal fluid, since larger (five times) quantities of fluid were used in performing the reaction. A negative response should not be accepted as decisive until the technic with a larger amount had been used. In conclusion, he emphasized the value of the examination of the cerebrospinal fluid in both the study and the treatment of syphilis. The serum Wassermann should be used as a routine in the physical examination of all patients, with or without a history of venereal diseases. A positive reaction should be followed by a lumbar puncture with a study of the fluid in order to determine whether the nervous system was implicated. The treatment should not be suspended until after a systemic course of treatment and only after a negative Wassermann reaction in the cerebrospinal fluid to the larger amounts of fluid.

Medical Aspects of Cancer.—Dr. L. Duncan Bulkley, of New York, said that cancer was not a surgical disease, although it was true that the local results of the cancerous process might be removed by surgical measures, that the wound might heal primarily, and in some proportion of instances the tissues might remain sound. But experience had shown that the mere removal of the cancerous tumor and adjoining tissues surgically did not insure that the disease would not return in or near the scar, or elsewhere. It was well recognized and acknowledged that about ninety per cent. of those affected with cancer died from that malady. Surgery as a cure for cancer had been tried in the balance and found wanting, since under the supervision and treatment the death rate had increased to a lamentable degree of late years. According to the United States mortality reports, the deaths from cancer under surgical control had increased steadily and alarmingly since 1900, when they were sixty-three in 100,000 of the population, to 79.4 in 100,000, in 1914, or over twenty-five per cent. During the same period the mortality from tuberculosis, under intelligent medical supervision, had diminished from 201.9 to 146.8 in 100,000, or over twenty-seven per cent., making an actual difference of over fifty per cent. in their relative mortality since 1900. At this rate the deaths from cancer would outstrip those of tuberculosis in fourteen years more. Was it not time for them to consider whether the present attitude toward cancer was correct or not? The points thus far acknowledged by those who had most deeply studied cancer were both negative and positive.

Metabolism in Gout.—Dr. Nellis B. Foster, of New York, propounded two questions for discussion: 1. The cause of the increase of uric acid in the blood; and, 2, the explanation of deposits of uric acid in cartilages. In gout, as in health, the sources of uric acid were known and did not differ; there was no new source of supply. All the evidence indicated that man was unable to destroy uric acid once formed. Man resembled birds in respect to his purin metabolism. It seemed likely then that the uric acid increase in the blood in gout was due to a defect in excretion. The same increase in the blood was noted in renal disease. For the deposition of uric acid as tophi, no explanation was at hand. It was not due to the blood being saturated, since this was not the case; serum dissolved more uric acid than water because of the phosphate content. The explanation was probably to be found in the chemical state of uric acid, which existed in two forms in many animals, free and combined. This was not demonstrated in man as yet, but evidence pointing to this conclusion was accumulating.

Treatment of Gout.—Dr. Arthur F. Chase, of New York, said the determination of uric acid in the blood was an aid to the diagnosis of gout and served as a guide in its treatment. A list of cases showed an accumulation of uric acid in the blood, about three mg. in 100 c. c. in patients with clinical gout, and below this figure in cases of infective arthritis and neuritis. The differential diagnosis between the uric acid retention of incipient nephritis and gout was made by clinical symptoms. The treatment was directed toward lessening the formation of uric acid and facilitating its elimination. A table was shown illustrating the amount of uric acid reduction due to dietary restrictions and to the administration of salicylates and atophan. This table also showed that the elimination of uric acid was not increased by giving quinine, colchicum, or diuretin. Alcohol, tea, and coffee caused retention

of uric acid in the blood. A purin free diet was given containing all foods except meat, meat extracts, peas, beans, spinach, tea, coffee, and alcohol, and an accessory diet consisting of meats and fish of which the uric acid forming possibilities were known, being based upon the fact that 100 grams of roast beef produced 0.14 mg. of uric acid, of which approximately one half was excreted by the urine. By determining, according to the suggestion of von Norden, the eliminative capacity of the body for exogenous uric acid, it was possible to keep the intake of purins well within the limit. Or, according to Umber, the number of days required to eliminate the uric acid arising from a definite amount of purin substance could be ascertained, and articles on the accessory diet given at such intervals that retention of uric acid was avoided. For practical purposes these methods had proved cumbersome, particularly as they necessitated the accurate collection of twenty-four hour specimens of urine and the careful weighing of prepared diets, and were being superseded by the simpler procedure of examining the blood for uric acid The continuous use of alkaline drinking waters induced a deposition of sodium biurate in the joints and cartilages and was capable of precipitating an acute attack of gout. The value of the periodical administration of atophan or, in nonnephritic cases, of salicylates, in depleting the blood temporarily of uric acid, was emphasized as a means of giving symptomatic relief and preventing the deposit of uric acid in the joints, thereby aborting acute gouty attacks. Exercise, massage, and hydrotherapy assisted in the elimination of uric acid, while the treatment of acute attacks was limited to the giving of colchicum, large doses of hydrochloric acid, salicylates, water, and the application of soothing lotions.

Dr. Julius Schiller, of Amsterdam, said it seemed to him that they were just drifting in medicine and surgery. Many eloquent papers had been read and they showed that physicians knew what should be done for these children, but they were unable to do the things that ought to be done because they did not have the means. The medical inspector knew the children in his schools that needed glasses or needed to have other defects corrected, but the parents did not have the means to have the work done. They could not do much until basic economic conditions in the home were improved.

Dr. A. P. Squire, of Rotterdam, was interested in the significance of Hutchinson's teeth. He asked if any one had tested for the Wassermann reaction in children having Hutchinson's teeth, and if any one had found out just what this sign signified in school children.

Doctor Howe said no one had called attention to the effect of coffee and tea drinking in relation to the nervous conditions that had been discussed. In his work he had found that a very large proportion of children drank tea and coffee, even in families that were fairly intelligent.

Dr. John Heffron, of Syracuse, said the question asked in regard to Hutchinson's teeth was important. These cases frequently came under his observation, and he felt that the sign known as Hutchinson's teeth was sometimes due to a delay in the eruption of the teeth. He had not been able to discover that any one had made observations on this point.

Doctor Howe said that the State Department of Health stood ready to make the Wassermann test. They had found a reasonable number of children with syphilis and had treated them successfully.

Doctor Whitbeck said that the examination of the teeth was very important. In orthopedic work all cases of arthritis were examined by the x ray in order to ascertain the condition of the teeth. When a focus of infection was found in a socket of a tooth, the patient was put under treatment until the condition cleared up. In a goodly number of cases, if the focus of infection was not removed, a chronic rheumatism developed. Frequently, when there was an abscess at the root of a tooth, the dentist wanted to save the tooth, but he thought it was better to pull the tooth out, since, if the source of infection was not thoroughly removed, the condition might progress and lead to permanent disability.

Dr. L. Duncan Bulkley, of New York, had noted that nothing had been said as to the importance of thorough mastication. Mothers should be instructed to teach children to chew their food properly; they should insist on a child staying at the table fifteen, twenty minutes, or a half an hour. Some device, as aluminum or celluloid balls or a cardboard cuff around the upper arm, would prevent the child from thumb sucking.

The Value and Limitations of Physiological Therapeutics.—Dr. John M. Swan, of Rochester, said that the various forms of modern hydrotherapy, gymnastics, massage, passive motion, etc., were the direct descendants from an ancient cult which flourished so long ago in the hills of the Argolic Peninsula. It must not be supposed, however, that it would do today to tell a patient to go to a health resort and take a few baths. The details of the various forms of treatment employed must be studied and understood, and careful prescriptions must be written for the kind and duration of the treatment desired. In this day of scientific research into the causes of the various effects following different forms of treatment, it would no longer suffice to say, as it was said many thousand years ago, that the value of the waters at Apidaurus depended upon some drops of gorgon's blood which had been given Æsculapius by Athena, nor would it do to ascribe the benefits to changes in metabolism when no metabolic studies had been made, to influences on the skin, heart, and blood pressure, not backed up by figures, to the influences of salts, gas, etc., in the water, not confirmed by control experiments with plain water. Doctor Swan quoted a few paragraphs taken from Honan's paper, published in 1910, entitled Bad Nauheim: Its Treatment and Therapeutic Value: "There is so much of real therapeutic value in the baths of Nauheim that I know all progressive practitioners of today will appreciate a truthful and unprejudiced opinion of the most recent studies of these waters. It is a well known fact that carbonic acid baths have a special action on two organs of the human body—the heart and the skin. The heart is strengthened by the increased flow of blood in the

coronary arteries due to the action of the carbonic acid on the vasomotor nerves and the increase in the coronary circulation. To the presence of certain salts is due the activity and great therapeutic activity of these Nauheim baths. The carbonic acid, as we know, greatly accelerates the action of the calcium and sodium salts."

Doctor Swan then reported several cases that he had treated with the brine baths, carbonic acid baths, and with fresh water only. In one case of a male, aged fifty-one years, who was suffering from a moderate amount of cardiac hypertrophy with beginning arteriosclerosis, the water in the fourth bath, instead of the usual one sixth dilution of brine, was fresh. The patient observed no difference. This was an example of several other cases in which the patients noticed no difference in their condition from these baths and in which the pulse rate was not affected. Doctor Swan said that his object in presenting the subject in this manner was not to discredit physiological therapeutics, but to endeavor to stimulate those who were engaged in the administration of health resorts to study the effects of the methods employed by every method obtainable, so as to provide some accurate basis for the statements made. They should try to get away from mysterious statements whether it was gorgon's blood or radium, to get away from commercialism which tried to make patients believe that x spring was the only place in the world where the patient could get well.

Further Report on the Technic of Abdominal Cæsarean Section.—Dr. William M. Brown, of Rochester, said this subject had been presented by him when he proposed a modification of the Davis operation into an extraperitoneal one. The present technic had been evolved on account of the evil effect of manipulation of the intestines, which accompanied most abdominal surgery. Every operator recognized the need of packing the cavity with gauze to keep the uterine contents from spilling into it, and also the necessity of keeping the abdominal wall firmly against the uterus. Assistants experienced great difficulty in holding these together until the child was safely delivered. He found that patients who suffered most from shock, distention, and pain were those who had had most traumatism and handling in the peritoneal cavity. To avoid the slipping down of the uterus in the pelvis before the incisions were closed, he had devised a method of temporary suturing of the uterus to the abdominal wall, so that an assistant could be dispensed with. This prevented emptying of the uterine contents and protected the viscera from handling. At first he feared excessive hemorrhage might result, but he found that bleeding was more easily controlled than in pelvic delivery. Later he simplified the procedure still more by the use of four to six of the ordinary power clamps of Moynihan or Backhaus, and fastened the uterus firmly to the abdominal wall instead of using sutures. In an analysis of fifteen cases treated in that way there had been no deaths and recovery had been remarkably smooth and free from vomiting and distention. His conclusions were, therefore, that fixation of the uterus to the abdominal wall before delivery possessed distinct advantage to the patient, protecting both from infection and from subsequent pain and discomfort; second, that patients who underwent this operation did not suffer more hemorrhage than under the old form of operation or of pelvic surgery.

Dr. J. Wesley Bovee, of Washington, D. C., would like to know the method of treatment, of the abdominal wound and the uterine wound in operating in these cases of suspected infection.

Dr. Sylvester J. McNamara, of Brooklyn, asked by what method Doctor Brown applied the forceps; how much abdominal wall was included in the grasp of the forceps? Had Doctor Brown any experience with tearing of the uterine wall by such forceps?

Dr. A. B. Miller, of Syracuse, knew how sincere Doctor Brown was in his work and the interest he had shown, but he felt that every man became subject to a method and Doctor Brown had become subjected to this method of fastening the uterus to the abdominal wall. Did Doctor Brown select the cases where he suspected infection, or did he apply this method in all his cases? Generally, he felt that there was no great risk of infection in the uterine contents. They would not give rise to infection in the peritoneal cavity, although they might give rise to endometrial trouble. This method was successful in the hands of Doctor Brown. The method of Davis of upper abdominal operation, however, prevented adhesions. They might do Cæsarean sections many times and not have infection. He felt that nothing particular was gained by fastening the uterus to the abdominal wall. Infection was not likely here, it might do harm in the endometrium, after the placenta had been removed, and then would be more serious than in the peritoneum.

Dr. William Bryan, of West New Brighton, had had better results since he had been doing the Davis operation with high incision, and had paid little attention to the contents of the uterus, whether they escaped or not. He had had no occasion for regret. He had not clamped the abdominal wall to the uterine wall. He had had experience in getting an assistant to keep the uterus from getting down into the pelvis. He made a special point of telling the assistant to keep his finger in the upper angle of the uterine wall and let him (Doctor Bryan) do the rest. He had attempted to suture the uterine wall to get a mechanical grip, but it took extra time and traumatism. If they succeeded they had not accomplished much. The uterine contents did not do much harm. Careful technic, rapid operation, and a simple procedure, with less delay and less traumatism gave the best results.

Doctor Brown was grateful for the discussion of his method. In regard to Doctor Bovee's remark about the treatment of the incision and suspected infection, he had practically made no difference, that was, unless he was certain that there was no infection. He had had one case of infected uterus in a hysterectomy. He did not know the patient had fever, and she was already on the operating table and he was not told until the operation was finished. He was impressed with the fact that while the woman had a severe sepsis, chills lasting twenty-five minutes, temperature 106° F., there was no infection of the peritoneum; it was a pure septicemia. She got perfectly well.

In regard to tearing of the uterine wall, which

Doctor McNamara spoke of, he had had nothing of that kind. They had used Guy sutures, which tore out because they did not go in deeply enough into the abdominal wall, but since the use of clamps, the assistants placed the clamps before he completed the incision through the uterus. The clamps did not go into the endometrium at all. The abdominal incision was made and then the uterine, and the assistant picked up a comfortable portion of the uterine muscle and the whole abdominal wall half an inch from the edge of the incision and clamped it. He then finished his cut through the uterus. The main question was not so much of infection as it was of handling the intestine; after the uterus was emptied it contracted and the intestines would override unless they took a whole towel to pad them off. He then closed the uterine incision, but many operators under such conditions put in a whole towel to keep out the intestines.

The Influence of Luetic Invasion in Gynecology and Obstetrics.—Dr. J. Wesley Bovee, of Washington, D. C., said that syphilis was to be found about eight times as frequent as admissions stated. There was found to be an alarming prevalence of lues among those who denied it, or who presented no symptoms. Morrow and Neisser stated that five per cent. of the German population and two per cent. of the population of the United States had been infected. In 619 cases collected from gynecological and obstetrical clinics there was a probable total of thirty-eight per cent. infections; about sixty per cent. of those were in white women. Luetic infection in females was much more obscure and easily overlooked or mistaken for other conditions than in the male. Cervical chancre closely resembled erosions and infiltrations. In one case seen there was marked resemblance to cervical cancer. Local manifestations of luetic invasion of the female genital tracts were slight and disappeared without leaving a trace. Tertiary lesions of the cervix, however, were sometimes seen. Possibly spermatozoa carried spirochetes into the ovaries and tubes, but thus far this was not proved.

Considering the relationship of lues to obstetrics, which was highly important, they could discuss the probable routes of infection from mother to child, and also the value of Colles's law, which should be subjected to revision. He felt that there was no such thing as a healthy mother with a syphilitic child, and vice versa. Infection was latent in one or the other. He felt that once a diagnosis of lues was established, treatment should be as vigorous as was compatible with safety. It would seem beneficial perhaps to regard all patients as at least mildly luetic, and to apply antiluetic treatment.

Dr. Thomas J. Watkins, of Chicago, as to the frequency of lesions on the cervix, believed it to be greater than stated. This emphasized the risk of examining patients without gloves and also the importance of sterilization of instruments between the examination of one patient and another. He had not seen many physicians' offices fully equipped for sterilization of instruments, so that they depended upon some simple chemical agent for sterilization. It was not too much to say that all obstetrical and gynecological cases should have the Wassermann test. One of the most important questions of today was how often patients should have the Wassermann test and what class of cases should have it. Two papers had appeared which brought out very emphatically the need of this test. A man who had made examinations of 4,000 cases found that of those with a positive Wassermann fifty per cent. were women in whom syphilis was not suspected.

Dr. George Gray Ward, of New York, said the matter was of interest in regard to the question of Colles's law which they had been led to believe had proved incorrect. At a recent meeting in Washington, however, Dr. Whitridge Williams reported a case which seemed to prove that this law might hold good. He had had a case in his service of a negress who had had eleven labors under his control. She had had repeated Wassermanns but all were negative. The first five labors were perfectly normal, the sixth was a twin birth, and one child was markedly syphilitic and one not. This was probably a case of superfecundation. Subsequent labors under observation gave no evidence of syphilis. The woman never showed syphilis. If the woman had two lovers at the time of conception it would be the strongest evidence that there was reason to believe in the validity of Colles's law.

Results and Technic of Vaginal Subtotal Hysterectomy for Procidentia and Cystorectocele Associated with Fibroid Growths or Fibrosis uteri.—Dr. Hiram N. Vineberg, of New York, in a method previously described, had dealt with amputation of the body of the uterus at the internal os and the use of the cervical stump to hold up the bladder by anchorage to the subpubic fascial ligament. That method possessed advantages over total hysterectomy, and was attended by less hemorrhage. At that time ten cases had been treated in that way, but since then twenty additional cases had been operated in. The technic was as follows: 1. Longitudinal incision of the anterior vaginal wall, extending from near the urethral meatus within an inch or an inch and a half of the cervical os. 2. Separation by sharp or blunt dissection of the vaginal walls from the underlying bladder. 3. Pushing of the bladder up from the uterus and base of the broad ligament by gauze dissection. 4. Transverse incision of the vesicouterine peritoneal fold. 5. Delivery of the body of the uterus through the vaginal incision. 6. If the ovaries were to be preserved, a ligature was passed around the ovarian ligaments and the tissues were cut between the ligature and the uterus. If they were to be removed, the ligature was passed around the infundibulopelvic ligament. 7. A ligature was passed at the level of the os internum, the body of the uterus was amputated at the desired level by a wedge shaped incision, the thin edges of the wedge toward the cervix; the edges of the wound then brought down by continuous catgut suture and the raw area of the cervix sutured laterally in the same way. 8. The cervical stump was then sutured to the subpubic fascia and anterior vaginal wall. Further modifications of this operation would be the shortening of the uterosacral ligaments to prevent the cervical stump from pushing

downward. Of thirty-two cases, twenty-five had given excellent results. One was a failure.

Technic of Vaginal Plastic Operations for Cystorectocele and Prolapse of the Uterus.—Dr. R. T. Frank, of New York, said this was an attempt to standardize technic. The technic was described which in ten years had given more uniform results and which was most readily taught to most surgeons in a hospital. The operation for cystocele was as follows: The anterior lip of the cervix was seized with volsellum and pulled to the vulva; the mucosa was seized with artery forceps half an inch below the mucosa; the mucosa was incised between the two fixed points and resected on both sides half an inch along the line of incisions superficially; neither deep nor wide reflection was permissible; narrow flaps on each side were seized with two forceps by an assistant; at the lowest angle of the wound the bladder was freed from the cervix in the median line by the snips of scissors; the bladder was freed by pushing firmly up against the cervix until the lateral fibres became more plainly demarcated. After exposure of these bladder pillars the vaginal flaps were to be separated more widely; a thin line of fascia continuous with the pillars was to be preserved. The repair was to be done as follows: Two transverse sutures of medium chromic catgut were passed, taking in first one pillar, then the cervix, then the opposite pillar; the upper suture was passed at the lower border of the peritoneal reflection, the next one half inch below it; the pillars were united firmly in the median line by tying, thus raising the bladder to a higher level and making it flat instead of bulging.

For rectocele the repair was as follows: After exposure, the rectum should be pushed away from lateral structures with the finger. The approximation should take place at the descending ramus of the pubis. The rectum should be passed, taking in the lateral fascia and underlying muscle on one side, then forming a partial pursestring suture, grasping the rectal fascia between the rectum and mucosa around the upper part of the rectocele, and again grasping the lateral structures on the opposite side, the suture being tied. The rectum was thus firmly fixed and held back. The gap in the mucosa should then be sutured with interrupted sutures, as this region later became less accessible.

The Pessary in Retroversion and Prolapse.—Robert L. Dickinson, of Brooklyn, said the pendulum swung from one extreme to the other. In former times it swung too much toward the pessary treatment, and now it swung too much to the surgical side. They often heard sweeping condemnation of pessaries, but it could be safely said that there were a great many cases of retroversion that were practically symptomless, that could well be left alone. In the group that could be taken care of by pessaries there should be included, first, the retroversions of early pregnancy; second, post partum retroversions; third, bad risks; fourth, a few cases where retroversion had affected the bladder. In regard to the first group of cases, a physician should examine his patient early, between the first and second omitted periods.

(*To be continued.*)

Book Reviews

[We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.]

A Treatise on Blood Pressure in Ocular Work. With Special Reference to Factors of Interest to Refractionists. By Eugene G. Wiseman. Illustrated with 19 Engravings. Rochester, N. Y.: John P. Smith Printing Company, 1916. Pp. xviii-267.

The particular purpose of this work is to acquaint optometrists with some of the facts relative to blood pressure and their bearing upon the refractive and muscular conditions of the eye. It is interesting in connection with the assertion so persistently made that optometry is not a part of the practice of medicine, to note this emphasized sentence in the preface: "If it is important to detect such diseases with the ophthalmoscope after the destruction has taken place, is it not far more important to detect symptoms of the fundamental causes of such disturbances in time to avert the impending disaster?" Not only is the answer obviously affirmative, but the corollary is just as obvious, that no one should practise optometry until he has had a thorough instruction in physiology, pathology, and treatment; in other words, in the practice of medicine.

This conclusion is emphasized strongly as soon as one reads the book, which is divided into two parts, the first presenting the general facts of arterial anatomy, histology, physiology, pathology, and sphygmomanometry, the second dealing with the relationship between general and ocular pathology. In the latter we find discussions of diseases of the circulatory, digestive, and urinary systems, anemia, diabetes, chlorosis, exophthalmic goitre, and syphilis, as well as the effects produced by tobacco, alcohol, and atropine. The writer evidently has read widely, and yet either has or appears to have only a superficial knowledge of his subject. This is not astonishing if he has pursued his medical studies unaided, for those of us who are well acquainted with these studies know that their depths are not reached easily, and that many fallacies lie on the surface ready to trip every one into error. We wish we could recommend the book, for its author has made a strong effort to bring into prominence matters that are of importance. As it is, the only thing we can do is to recommend him to take a full course in some Class A medical school, allow himself time to digest the knowledge acquired there and to appreciate its bearings on his own observations, and then to try again.

Transactions of the American Surgical Association. Volume the Thirty-third. Edited by John F. Binnie, M. D., Recorder of the Association. Philadelphia: William J. Dornan, 1915. Pp. xxviii-825.

This volume, containing the papers read before the association at the meeting held June 9 to 11, 1915, is a valuable addition to any physician's library, as it embraces articles by many of the best known surgeons in the United States. The address of the president, Dr. George E. Armstrong, is unusually well written and the fact that he is a Canadian accounts for his interest in military surgery at this time. He gives a brief review of its history. Of the forty papers nine deal with the surgical complications of typhoid fever and with the surgery of the spleen. The gallbladder and breast follow in order of prominence.

Interclinical Notes

The *Nurse* for July, 1916, pays itself a few well deserved compliments on the success which has attended its two years of existence. This issue explains the success. Dr. Conduct W. Cutler, Jr., writes on Homemade Surgery, Dr. Thompson Frazer on the treatment of tuberculosis, Dr. Francis Carter Wood on cancer, Dr. Anne E. Perkins on nursing the insane, Dr. W. S. Birge on amnesia, while a large and well trained chorus of nurses supports these stars by valuable contributions on the accomplishments, vocational and avocational, of those who attend the sick or wounded. The scenic setting, so to speak, is admirable,

particularly in the act concerned with diet; the prognosis would be very grave where a patient refused to consider any of the trays photographed for this department.

* * *

From page 767 of *Commerce and Finance* for July 5th, we learn that in talking airily for all these years about sisal, we have been exposing our ignorance and have probably been well laughed at by experts; hereafter we shall always call it henequen and will refuse firmly and knowingly to pay more than six cents a pound for it.

Official News

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the two weeks ending July 8, 1916:

Cook, F. C., Surgeon. Detached from the *Louisiana* and ordered home to await orders.

Curl, H. C., Surgeon. Detached from the *Alabama* and ordered to the *Rhode Island.*

Dragoo, C. H., Assistant Surgeon. Ordered to the Naval Hospital, Newport, R. I.

Dunbar, A. W., Surgeon. Detached from the Naval Academy, Annapolis, Md., and ordered home to await orders.

Richards, T. W., Surgeon. Ordered to duty with the Military Relief Division, American Red Cross, Washington, D. C.

Stuart, M. A., Passed Assistant Surgeon. Detached from the *Wilmington* and ordered home to await orders.

Taylor, J. S., Surgeon. Detached from the *Rhode Island* and ordered to the *Alabama.*

Wilson, Talmadge, Assistant Surgeon. Detached from the Naval Hospital, Yokohama, Japan, and ordered to the *Wilmington.*

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers in the United States Public Health Service for the seven days ending July 5, 1916:

Draper, W. F., Passed Assistant Surgeon. Granted one month's leave of absence from July 10, 1916.

Foster, M. H., Surgeon. Granted one month's leave of absence from July 5, 1916.

Francis, Edward, Surgeon. Granted three days' leave of absence from June 26, 1916.

Grimm, R. M., Passed Assistant Surgeon. Detailed to deliver an address on public health at the Chautauqua to be held at Pickens, S. C., July 11, 1916.

Knight, C. P., Passed Assistant Surgeon. Directed to proceed to Pensacola, Fla., Quarantine Station, and assume temporary charge.

Lanza, A. J., Passed Assistant Surgeon. Detailed to attend a meeting of the Montana Medical Association at Miles City, Mont., July 10, 1916.

McKeon, F. H., Passed Assistant Surgeon. Granted one day's leave of absence from July 11, 1916.

Oakley, J. H., Surgeon. Granted three days' leave of absence from June 24, 1916, under paragraph 193, Service Regulations.

Pettus, W. J., Surgeon. Granted leave of absence for one month and six days, from July 17, 1916, with pay, and twenty-four days without pay, from August 23, 1916.

Preble, Paul, Passed Assistant Surgeon. Detailed to deliver an address on public health in rural communities at the annual school of health officers, at Burlington, Vt., July 6-7, 1916.

Robinson, D. E., Surgeon. Granted one month's leave of absence from July 8, 1916.

Stimson, A. M., Surgeon. Granted one month's leave of absence from July 6, 1916.

Williams, L. L., Senior Surgeon. Bureau letter dated May 23, 1916, granting one month and fifteen days' leave of absence from July 1, 1916, amended to read one month's leave of absence from July 18, 1916.

Yarbrough, H. C., Assistant Surgeon. Directed to proceed to Liberty, Mo., to conduct studies of rural sanitation in Clay County.

Births, Marriages, and Deaths

Born.

Bates.—In Morrisville, Vt., on Saturday, June 24th, to Dr. and Mrs. George L. Bates, a son.

Married.

Ball-Mauck.—In Burton, Ohio, on Saturday, June 24th, Dr. Clay A. Ball, of Muncie, Ind., and Miss Helen E. Mauck.

Beatty-Snyder.—In Trenton, Mo., on Wednesday, June 21st, Dr. Jesse Beatty, of Farragut, Iowa, and Miss Pearl Snyder.

Blaisdell-Rose.—In Brooklyn, N. Y., on Saturday, July 1st, Dr. Silas C. Blaisdell and Miss Mary E. Rose.

Broughton-Leavitt.—In Exeter, N. H., on Thursday, June 29th, Dr. Henry White Broughton, of Boston, Mass., and Miss Mary Lawrence Leavitt.

Finney-Wheeler.—In Fairfield, Conn., on Thursday, June 29th, Dr. William Finney, of Baltimore, Md., and Miss Theodore Wheeler.

Keough-Clark.—In Pawtucket, R. I., on Tuesday, June 27th, Dr. Peter L. Keough and Miss Mary G. Clark.

Kickham-Keating.—In Boston, Mass., on Wednesday, June 28th, Dr. Charles Joseph Kickham and Miss Mary Keating.

Malcolm-Murphy.—In Fairfield Beach, Conn., on Saturday, June 24th, Dr. F. L. Malcolm, of Yonkers, N. Y., and Miss May Murphy.

Martin-Cook.—In Plymouth, N. H., on Monday, June 19th, Dr. Harold W. Martin, of Dorchester, Mass., and Miss Mildred Harlowe Cook.

Monahan-Casey.—In Providence, R. I., on Wednesday, June 21st, Dr. John T. Monahan and Miss Mary Casey.

Ott-Roulstone.—In Chelsea, Mass., on Friday, June 16th, Dr. George J. Ott, of Boston, and Miss Mary S. Roulstone.

Sullivan-Jones.—In Woodbridge, N. J., on Wednesday, June 28th, Dr. Charles Joseph Sullivan, of New Brunswick, N. J., and Miss Anabel E. Jones.

Weed-Tovey.—In New Haven, Conn., on Monday, June 26th, Dr. Arthur R. Weed and Miss Alice Tovey.

Died.

Aultman.—In Meigs, Ga., on Thursday, June 22nd, Dr. I. R. Aultman, aged fifty-six years.

Anselme.—In St. Louis, Mo., on Friday, June 30th, Dr. Francis B. Anselme, aged fifty-five years.

Blundell.—In Allendale, N. J., on Friday, June 30th, Dr. William Blundell, of Paterson, N. J., aged eighty years.

Brooks.—In Washington, D. C., on Sunday, June 25th, Dr. Floyd Vernon Brooks, aged sixty years.

Clarke.—In Amherst, Mass., on Thursday, June 22nd, Dr. George S. Clarke, aged sixty-two years.

Corrigan.—In Providence, R. I., on Friday, July 7th, Dr. John P. Corrigan.

Coues.—In Cambridge, Mass., on Monday, May 1st, Dr. S. F. Coues, Medical Director, United States Navy, retired.

Eaton.—In Lowell, Mass., on Sunday, June 25th, Dr. Wyllis G. Eaton, aged sixty-two years.

Etheredge.—In Wagener, S. C., on Saturday, June 24th, Dr. Luther B. Etheredge, aged forty-five years.

Johnson.—In Newark, N. J., on Saturday, July 1st, Dr. William Mapes Johnson, aged eighty-one years.

Jones.—In Memphis, Tenn., on Monday, June 26th, Dr. Heber Jones, aged sixty-eight years.

Long.—In Carlisle, Pa., on Sunday, July 2nd, Dr. John Coover Long, aged sixty-nine years.

Niles.—In Springfield, Ohio, on Saturday, June 24th, Dr. Lewis E. Niles, aged fifty-four years.

Nolen.—In Baltimore, Md., on Friday, June 30th, Dr. Charles F. Nolen, aged forty-eight years.

Watkins.—In Spring City, Tenn., on Sunday, June 25th, Dr. Reece Kelso Watkins, aged sixty-seven years.

Whitbeck.—In Rochester, N. Y., on Monday, July 3rd, Dr. John F. W. Whitbeck, aged seventy-two years.

Wood.—In New York, on Thursday, July 6th, Dr. Charles S. Wood, aged fifty-two years.

Woodward.—In New York, on Sunday, July 2nd, Dr. Julius H. Woodward, aged fifty-eight years.

THE DIAGNOSIS AND TREATMENT OF ACUTE ANTERIOR POLIOMYELITIS IN THE PREPARALYTIC AND POSTPARALYTIC STAGES.*

BY M. N. NEUSTAEDTER, M. D., Ph. D.,
New York,
Lecturer in Neurology, New York University and Bellevue Hospital Medical College.

While nothing new has been discovered about the epidemiology, etiology, diagnosis, and treatment of poliomyelitis since 1912, it might be apropos at the present time to reiterate some of the salient features with a view of suggesting some points in its diagnosis and treatment.

ETIOLOGY.

That the disease is infectious and contagious, no one will gainsay. We know that the virus belongs to the variety that can be filtered through a porcelain and asbestos filter and that it is highly resistant to many destructive measures; thus it withstands glycerinization for long periods, drying over caustic potash, freezing, and is not injured in a 0.5 per cent. phenol solution for three days. Gastric and intestinal juices seem not to affect it. On the other hand, it is readily destroyed when heated to a temperature of 50° C. for half an hour, or in weak solutions of hydrogen peroxide, formaldehyde solution, menthol, potassium permanganate, or corrosive sublimate. Several investigators have reported pure cultures of a coccus producing the disease, but this is as yet unconfirmed.

The mode of its infection can be accepted as fairly well established. Infections may be propagated either by the circulatory or lymphatic system. No evidence has as yet been adduced that the circulatory system is the primary route for the virus of poliomyelitis, while the evidence in favor of the lymphatic system seems to be conclusive. It was my privilege to be the first to prove that the nasopharynx was the point of entry, and later investigators produced the disease experimentally from the nasal discharges of patients as well as from healthy carriers.

It is then conceivable that its mode of dissemination may be through direct contact or indirectly through persons, living animals, or dead objects. House pets may carry the virus from place to place; toys, books, linen will likewise carry infection, and, most of all, dust is the greatest disseminator of the disease. This last agency was proved by me when I produced the disease experimentally in monkeys from dust of the sick room; this was fully confirmed by Swedish investigators. It may be that the fly carries the germ and thus spreads the disease, but it was not proved that insects act as hosts for the virus. Articles of food may be contaminated and may infect by coming in contact with the pharynx. Milk and also water may be carriers, since the virus has been shown to remain viable in them and retain its virulence for over thirty days. The nasal discharges are probably swallowed, and, as it was shown, the virus survives in the intestinal tract; it may, under certain circumstances, contaminate the sick room through feces.

The period of incubation is estimated to be from two to thirty-three days. I have one case on record in which I could establish a period of incubation of one day. It was in a physician's child and the father brought the infection after staying in the house of a relative with a poliomyelitic patient for thirty-six hours. Twenty-four hours after he had arrived home, his child was stricken with fever, which lasted two days. On the third day, the child's lower extremities became paralyzed.

As to age, the statistics vary. In Europe five per cent. of all patients are over sixteen years of age; in this country not more than one per cent. of all patients are over sixteen years old. Both sexes seem to be equally attacked. Poliomyelitis, furthermore, shows definite seasonal variations in its incidence. The records of epidemics in many countries show that it occurs during the summer and reaches its maximum in the late summer and early autumn. Sporadic cases occur everywhere throughout the entire year. Our present epidemic started rather early in the season, owing probably to the high virulence of the virus.

It is significant that, while the disease is highly contagious and infectious, we find, comparatively speaking, not many cases of infection during an epidemic in proportion to the population of an affected community. It is rarely that more than one member of a family is attacked at a time; few nurses were infected while attending cases in hospitals, and the epidemic recurs only every three to five years in the same locality. It may be due, as some authors argue, to an acquired active immunity.

*This original communication was written by special request of the NEW YORK MEDICAL JOURNAL.

I believe that it may also be due to an inherited immunity and that individuals are affected who exhibit a point of minor resistance in the cerebrospinal axis. Within the last few years I have collected fifty cases from my clinic and private practice with a fairly trustworthy family history. These show 5.4 per cent. to have neuropathic or psychopathic taint. This high percentage, even in so small a number of cases, is more than a mere coincidence. While I do not regard it as conclusive, I believe it significant, and further inquiry along these lines seems to me advisable.

Before entering upon a discussion of the clinical picture I deem it necessary to review the pathology of the disease as we understand it today. This, like the symptomatology, we must divide into two stages—the preparalytic and postparalytic. It is well to remember, as I have pointed out recently, that poliomyelitis is a pathological entity, but not a clinical one. That is to say, it cannot be regarded as affecting the anterior horns of the spinal cord exclusively, but rather the entire cerebrospinal axis, the gray and white matter and the meninges as well. Nor are the other viscera to be disregarded, for in no small number of cases these are also affected; so that by recognizing that acute poliomyelitis is a general infection and that, in accordance with particular sites attacked, corresponding symptom complexes will appear, its course may be more easily explained and its bearing on treatment. Its pathology, however, is uniform and shows the same characteristics, no matter what part is affected. This is true of experimental and clinical cases alike.

PATHOLOGY.

In the prodromal stage we find macroscopically a hyperemia of the cord and meninges; the vessels of the brain cortex, basal ganglia, ventricles, pons, bulb, cerebellum, and cord at all levels, especially marked in the cervical and lumbar regions, are congested. The entire cerebrospinal axis presents an edematous condition. Yet there is little, if any increase of the cerebrospinal fluid. This is clear as a rule in this stage, and contains a large amount of polynuclears the first few days and then mononuclear cells—lymphocytes exclusively. The cell count may range anywhere from thirty to ninety cells per c. mm.; its globulin content is increased, and its reducing property for Fehling's solution, due to the presence of dextrose, is intense. The brain and cord, on section, have a moist, translucent, edematous appearance, and the gray matter of the cord is often swollen so that it projects above the level of the white matter. Frequently punctate hemorrhages may be discerned by the naked eye. Bearing in mind that the nasopharynx is accepted as the point of entry, we ought to find some evidence of this focus. Every clinician describing the clinical picture of acute poliomyelitis calls attention to the fact that there is no redness of the throat in the ordinary acceptance of the term; so all report the throat as negative. To my mind the throat is by no means negative. The paleness of the nasopharyngeal mucosa and its edema, accompanied in the early stage by a serous and frothy transudate, is constant in the affection and *pathognomonic* of the earliest prodromal stage. This is analogous to the edema of the brain and cord. I know of no affection in which such a condition of the pharynx obtains. Since the infant swallows the nasal discharges and some may enter the bronchi, we can explain at times the presence of foci of congestion in the lungs and alimentary tract. The virus, as I have stated, is propagated by the lymphatic system, and we may, therefore, have foci of congestion and edema in the various glands.

Histologically, the disease is characterized by a perivascular and interstitial infiltration of round mononuclear, polymorphonuclear, plasma, and endothelial cells. This is also true of the lymph spaces around the ganglion cells of the anterior horns of the cord, the cells of the nuclei of the cranial nerves, the cortical brain cells, basal ganglia cells and those of the cerebellum. Early in the disease there is also a marked infiltration of cells into the lymph spaces in the intervertebral ganglia. These and the vessels of the pia in the anterior longitudinal fissure of the cord are the very first to be involved. This has been experimentally demonstrated as early as the third day after infection. This infiltration follows along the sheaths of the central vessels of the cord into the anterior horns. Not infrequently we find an involvement of the vessels of the white matter of the cord as well, giving us a picture of transverse myelitis. In such cases the infiltration may be local or diffuse throughout. The capillaries of the gray matter of the cord are engorged. The degenerative changes in the ganglion cells in this stage are not great, but there is marked gliosis, especially of the wandering neuronophagocytes. Alterations of the peripheral nerves have not been described. There have been cases described in which the cell degeneration was marked in this stage, while the perivascular infiltration was scanty. These are exceptions. The first changes, then, are those of an acute interstitial meningitis, which is not associated with fibrin formation or with an exudate on the surface of the meninges. To summarize, the whole process is one of an inflammation. The blood early presents a leucocytosis with a predominance of polymorphonuclears, and, according to some investigators, mononuclears.

If the process goes on to the subacute or chronic stage, we find the following changes in addition to those enumerated. The perivascular exudate forms a sheath apparently completely surrounding the vessels for long stretches, pressing on the lumen of the vessel, and thus exerting a mechanical obstruction to circulation and thereby to cell nutrition. To this mechanical obstruction I ascribe the edema and one phase of cell degeneration. Devoid of nutrition, the cell swells up, the Nissl bodies coalesce, the nucleus becomes eccentric, and the cell finally breaks down, becoming autolyzed in its own ferment, there being no antiferment present to counterbalance it. There is also another phase of cell destruction. We find frequently a marked infiltration of the pericellular lymph spaces, with leucocytes predominating over the perivascular infiltration. These polynuclear cells and some mononuclears, probably polyblasts, enter into the ganglion cells with the probable purpose of destroying the virus therein. They are seen

on section in a degenerated state, caryorrhexia. These are the cells which absorb the products of degeneration of the ganglion cells and other leucocytes through phagocytosis. This is a characteristic form of degeneration of ganglion cells which we find in poliomyelitis. In place of the ganglion cells we find an accumulation of round cells. This process of cell destruction is termed neuronophagocytosis. Once the cell is destroyed, it is conceivable that later we should find a degeneration of its axone. As this process is becoming complete the whole anterior horn structure is converted into connective tissue; it shrinks and presents what older writers described as scars.

The ganglion cells of the anterior horns of the cord possess, beside motor, somatic functions also, and once destroyed must of necessity produce trophic disturbances in muscles and bones supplied by them; and the first to atrophy is the affected muscle. In later stages we find also involvement of bones.

A word about the question of immunity and the nature of the toxin of the virus. Various observers have found that the serum of a patient or animal recovered from the disease will neutralize the virus *in vitro* after being incubated for an hour in a temperature of 37° C. Such mixture, when injected into a monkey, will not produce the disease; nor will an animal again be successfully infected, in the majority of instances, after it has once recovered from the affection. Animals have been also rendered actively immune by successive vaccinations with the attenuated virus after the method of Pasteur. On the other hand, it was established that the serum of a recovered case had no protective or curative power whatever. As to the character of the toxin, we have so far established that, whatever exotoxin there may be, it is a negligible quantity and of no great toxicity. Nor does the endotoxin seem to be very toxic. This conclusion I have reached from my experiments and clinical data at hand. I have succeeded in separating the endotoxin and found that the product of a suspension of a virulent virus, of which 0.1 c. c. did bring down a monkey in six days, would kill a rabbit of 900 grams only when injected with fifteen c. c. Guinea-pigs immunized with such endotoxin have yielded a serum which rendered the virus *in vitro* inactive after an incubation period of three quarters of an hour in a temperature of 37° C. Whether such serum possesses any protective or curative properties remains to be seen at the conclusion of my work.

SYMPTOMATOLOGY.

Our difficulty lies mainly in the possibility of early diagnosis of the disease before the onset of paralysis. The importance of this cannot be overestimated, since it may afford us a means of attempting to intercede in time to prevent paralysis and, possibly, death. In searching, then, for a set of symptoms during the preparalytic stage that would prove a criterion, we must have recourse to its pathology in that stage. Bearing then in mind the picture described above, we may expect very early *fever* as the first sign, accompanied sometimes by vomiting, with or without diarrhea. Alongside of this there are, without exception, nasopharyngeal symptoms. Frequently we hear that the patient began to sneeze, or made attempts at sneezing, and at times this was accompanied by copious nasal discharges. Upon inspection we find a somewhat anemic, glistening edematous condition of the nasopharyngeal mucosa, with a serous, frothy transudate, analogous to the edematous swelling of the cord that we see upon autopsy. This condition persists for a few weeks after the paralysis had set in and then changes to an anemic atrophic condition of the mucosa. I desire to lay stress upon this sign as being, in my opinion, pathognomic of the disease at its onset, and, taking it in conjunction with other signs that I am about to enumerate, will enable the general practitioner, who is the first to be consulted, to diagnosticate the case early. With this sign present, it becomes imperative to make a lumbar puncture, and the cytological findings in the cerebrospinal fluid as enumerated will at once clear up any doubt.

Headache and pain ought to be, and as a rule are, constant accompaniments. The little infant cannot tell us of its headache, but he is giddy and drowsy, yet rarely comatose; the mentality is always clear, and the child is easily roused. This is in accord with my statement, that the exotoxin is of a negligible quantity and the endotoxin is not very toxic, or else there ought to be high fever and delirium, even coma. The older children, when affected, always complain of this characteristic headache and giddiness. These symptoms are due rather to the hyperemia of the brain vessels and the edema without appreciable augmentation of the cerebrospinal fluid.

It has been shown in experimental as well as clinical cases that the exudate in the intervertebral ganglia is marked early in the disease, and associated with this infiltration there is an inflammation of the dura of the cord. For these reasons there is, quite early, pain in the extremities and along the spinal column, a hyperesthesia along the affected area, and rigidity of the muscles of the neck. It should be remembered, however, that there is no pain on pressure along the course of the peripheral nerves of the extremities, unless it is a neuritic case, but rather on extending the affected limb. The children are found with their extremities in a flexed position, and an attempt to extend them, or even slight passive motion, produces excruciating pain—so much so that the patient cries from apprehension when only approached by the physician or nurse. The inflammatory condition, when extending to the brain meninges, may give rise to simple twitchings or even convulsions in direct proportion to the extent and intensity of the affection. The patients, as a rule, favor some extremity in particular, for there is the weak spot, and this favored extremity will become paralyzed. Reflexes may be weak or already absent. In some instances they are exaggerated at the beginning.

To recapitulate, then, we meet in the prodromal stage the following constant symptoms: Sudden onset with fever, headache, drowsiness, at times twitchings or convulsions, pain in extremities on passive motion and along the spinal column on pressure, sometimes gastrointestinal disturbances, the nose and throat symptoms, as mentioned, and the

cytological findings in the cerebrospinal fluid. Some investigators call attention to an early and profuse perspiration, but I cannot verify this.

In attempting to classify the symptom complexes of the subacute and chronic stages, we must bear in mind that in reality we are dealing not with an anterior poliomyelitis, but with a polioencephalomeningomyelitis. In these stages we get the end results of the infection; the symptoms indicate the site or sites of involvement anywhere along the cerebrospinal axis. In these stages some of the prodromal symptoms disappear, notably fever, headache, and the gastrointestinal symptoms, if such were present, and often pain also. All the symptoms may clear up and the patient fully recover. These are abortive cases and during every epidemic, the present one included, many such cases are reported. Most of the others that survive present several groups of paralyses, such as, 1, cerebral spastic; 2, bulbar cranial nerve involvement; 3, spinal flaccid paralyses; 4, pontine and cerebellar cranial nerve involvement, tremors, and ataxias; and, 5, mixed types. Of the cranial nerves the facial and acoustic are most frequently involved, the former resulting in Bell's palsy, the latter in deafness. The cerebral type is rare, and it is perfectly clear that if the sensoriomotor region is involved we shall have a spastic hemiplegia with or without epileptiform convulsions, or, if only the centre of one extremity is involved, a spastic monoplegia will result. In the spinal type we have, of course, the flaccid paralysis of one or more extremities, according to what segments are affected. Here the motor neuron emanating from the anterior horn becomes destroyed, causing a break in the spinal reflex arc, giving us a flaccid paralysis, loss of reflexes, wasting of the muscles, loss of response to the faradic current, and a positive reaction of degeneration. In the course of time this condition results in contractures, shortening of the affected limb, spinal curvatures and other orthopedic defects, abdominal and diaphragmatic hernias. The mixed types are those of bulbospinal or cerebrospinal symptom complexes. It seems to me that such classification reconciles the chief clinical symptoms with the predominant anatomical lesions.

TREATMENT.

Since the disease is directly contagious and is disseminated by healthy as well as sick carriers, prophylactic measures are essential. A strict quarantine for a number of weeks is, of course, the first requisite for the efficient protection of the public. Since I have shown that dust contains the virus in a viable condition, I advise a thorough scrubbing of the floors and frequent flushing of the streets and sidewalks. We must remember that people spit on sidewalks and children play there. On general principles I advocate the extermination of insects as possible carriers. Milk and other articles of food, where practicable, should be boiled. Domesticated animals and household pets should receive frequent washings. Bathing in stagnant water in an infected neighborhood, the playing of children around sand heaps in parks and their congregation in playgrounds or places of amusement during an epidemic should be prohibited. Since it was shown that the virus is readily destroyed by menthol and hydrogen peroxide, I strongly advise that the nasopharynx of the sick be frequently sprayed with a one per cent. solution of peroxide of hydrogen, and that of the healthy children be sprayed with a solution of 0.5 per cent. menthol in liquid petrolatum. As a measure of individual prophylaxis, this has given me good results in my practice. All these measures I advocated in the International Congress of Hygiene in Washington, D. C., in 1912. Since then it has been shown that feces contain the virus, and it would be necesary to disinfect these discharges, as well as bedpans and urinals. Bed clothes and other linen used by the patient should be thoroughly boiled.

During the febrile stage, complete mental and physical rest is imperative and should be continued so long as there is pain, for every movement causes discomfort. The patient, therefore, should be handled with extreme gentleness; we should avoid flexing the neck or hips, or extending the limbs, or even bending the spine. I would even forego sponging in high fever, in order not to cause pain by such manipulation. Bromides and chloral are, as a rule, efficient in alleviating pain in infants, but in older children the opiates or coaltar preparations will have to be resorted to in extreme cases. An exclusively fluid diet and mild catharsis, when necessary, should be carefully maintained. A cold compress to the head in temperatures higher than 102° F. proves soothing.

When the acute stage passes and paralysis sets in, a more active treatment must be instituted in order to prevent possible deformities and restore such muscular function as conditions may warrant. My guide as to when such active treatment should be begun is when pain subsides completely, and *not earlier*. So long as pain lasts, even with the fever gone, I immobilize the affected limb by putting it in a well padded splint, and patients are invariably grateful. I have seen many partial recoveries from loss of muscular function from such procedure. During the stage of active exudate manipulation of the extremity will cause fatigue in the nerve cells, and is apt to enhance the process of degeneration, while complete rest may, and frequently does hasten absorption of the exudate, and restitution *ad integrum* of nerve and muscle is made possible. All our spontaneous recoveries are due, in a great measure, to such precautions. Warm baths during the afebrile stage are of great benefit, and the patient should be left in the bath as long as he can remain with comfort—the longer the better. With the pain gone, about a fortnight after the onset of the paralysis, we may begin with massage, passive movements, and galvanism. No more than five minutes should be allotted to these measures daily, for the structures need very little encouragement and too much stimulation will easily exhaust them and produce the reverse of the desired effect. In using galvanism I prefer the interrupted to the continuous current, and then only of a weak amperage, just enough to produce contractions.

Active exercise of the muscles by the patient should be encouraged, and this is best accomplished with infants while bathing daily by putting into the

tub some floating toys and encouraging the patient to attempt to handle the objects with the affected limb. Older children can be persuaded to counteract antagonistic passive movements by the masseur. It may well be remembered that at times groups of cells in a given involved segment of the cord or cranial nerve nucleus may escape destruction and their function be restored, if thus encouraged. In this treatment we should persist for years. Several youngsters in my private and clinical practice who were hopelessly paralyzed for months, after persistent treatment for several years, have regained a fair amount of function in certain muscle groups. To avoid contractures, counteracting splints may be applied with advantage, but left on only part of the time at the beginning, for example, only over daytime, and removed at night. If no improvement is noticeable in any muscle group after persistent treatment for a few years, it is advisable to resort to operative measures, such as tendon transplantations or other surgical measures, as the case may demand. That the patient should at all times have a bland, well nourishing diet and plenty of fesh air applies here as well as in all febrile and wasting diseases. In common with all clinicians I recommend that we should *do all we can,* and at the right time, but in our zeal take care *not to overdo.*

DIAGNOSIS AND TREATMENT.

Old and New Methods,

By Adam H. Wright, B. A., M. D.,
Toronto, Can.,
Emeritus Professor of Obstetrics, University of Toronto; Chairman Provincial Board of Health, Ontario.

When Herophilus organized his medical school a little more than 2200 years ago, he attached special importance to the cardinal points in the teaching of the great Hippocrates—acute observation and careful interpretation of symptoms. In addition, he paid great attention to the sciences, especially anatomy, physiology, chemistry, and botany, and the Ptolemies assisted him by erecting great buildings, museums, laboratories, libraries, and botanical gardens. Their aims and methods compare fairly well with ours at the present time.

The writer desires in this paper to refer to certain phases in some serious diseases and conditions, and especially to show the importance of team work between the clinicians and laboratory workers. The fact that the majority of physicians in this part of Canada have great respect for such scientific workers as Amyot, Mabee, Fitzgerald, Mann, Lancaster, and others, and have much confidence in their good judgment, should materially assist us in getting good results both as to diagnosis and treatment. In brief reports of some illustrative cases names will not be mentioned, as a rule, although *ego* will creep in at times.

CERTAIN FORMS OF CANCER.

About twenty-five years ago, a diagnosis of condyloma was made at the Toronto General Hospital. A consultation was deemed advisable, and, as it turned out, there was a serious difference of opinion. Two competent men pronounced it epithelioma, and advised amputation. A specimen was sent to the laboratory, and the report given—epithelioma. I again investigated and talked the matter over with the microscopist. I found that he only expressed his opinion and did not pretend that this should be accepted without doubt. No operation was performed. After treatment, local and constitutional, the growth or growths melted away, and the man left the hospital in good condition. My clinical class followed this case carefully, and knew all about our doubts and fears. I tried to impress upon the students the importance of studying the case in all its aspects. When a specimen is sent to the laboratory, a full clinical history should go with it. The microscopist gave a wrong opinion in this instance, but in a majority of similar cases his opinion would be both correct and helpful. At the same time I mentioned the case of a woman with a tumor of the breast, which, I thought, was innocent. The microscopist proved to me that I was wrong, and the breast was amputated with happy results.

Two cases of hysterectomy will now be considered. A woman supposed to be near the end of the menopause had some hemorrhages which caused alarm. After a slight curettage the scrapings were examined with negative results. The symptoms were so serious, however, that the consulting surgeon advised hysterectomy. I was called in consultation, practically to decide for or against. I said yes, without hesitation. The operation was performed and a good recovery ensued. She is now happy and well, better, I think, than she could ever have been without the operation. The only criticism I should think of offering is that the curettage was unnecessary in this case and should not have been done. But one may ask, is that not going too far? In such a case surely a thorough investigation is advisable, and a slight curettage can scarcely do harm. My reply is, that it can do much harm. This patient for over twenty years was troubled with "nerves," and this "slight operation," although done gently and skillfully, gave her great pain and upset her seriously. As it turned out, it was useless, and in such a case therefore worse than useless. If the surgeon intends to operate regardless of what the laboratory may discover, surely curettage is unnecessary.

In the second case the patient was fifty-three years old, and had ceased to menstruate fifteen years before. She had serious hemorrhage for three months. Examination of uterine scrapings gave negative results, but because of the clinical symptoms the uterus was removed, and with the annexa was sent to the pathological laboratory for examination. After a few days a report came saying that decidual remains were found in the uterus, and a corpus luteum in one of the ovaries. This was considered "a good joke" on the surgeon, and reports spread through the city. The surgeon demanded a thorough investigation, which was allowed. Two pathologists of unquestioned reputation examined the specimen, and reported positively that there were no decidual remains, no corpus luteum, and that there was cancer. Apart from this

incident evidence had been accumulating for years that laboratory men in Toronto were constantly belittling the work of the clinicians as to their interpretation of symptoms. Of course a simple glance at the clinical report in this case would have prevented the possibility of such an enormous blunder, which might have blasted the reputation of an able surgeon, and also that of a decent woman.

A brief reference will be made to another case much more pleasing to contemplate. A few weeks ago a prominent physician of Toronto had symptoms of inflammation within the abdomen. After section a lump was found connected with the colon. Judging from the clinical symptoms it seemed likely that it was inflammatory in character. The laboratory findings were at first doubtful and sarcoma was suspected. Then four pathologists took hold, and after efficiently studying the specimen, decided that it was inflammatory. While I may not mention names in this paper, it will probably do no harm to say one of them was Welch of Johns Hopkins. Probably all connected with this case were inclined to thank Providence for the modern laboratory, which even in these days contains many men who are as careful and thorough in their methods as were Pasteur and Lister in their best days.

One of the scientific instruments which, as every one knows, has come into pretty general use is the sphygmomanometer, and along with it a good many remedies for the treatment of abnormal blood pressure.

Very careful laboratory investigations were conducted in various countries with a view to discovering a remedy for high blood pressure. The different forms of treatment which developed may be placed under three headings:

1. Administration of medicines that reduce blood pressure, such as potassium iodide, or such modifications as iodopin and the nitrites. A favorite combination in some parts of England is:

℞ Sodii nitritis, ...gr. ss;
Erythrol tetranitratis, ...gr. ¼;
Mannitol nitratis, ...gr. ¼;
Ammonii hippuratis, ...gr. 1.
M. Ft. Mistura.

2. When the heart begins to fail because of these depressing remedies, some therapeutists endeavor to build up with digitalis, strophanthus, etc.

3. Avoid certain kinds of food, overeating, constipation, tobacco, and alcohol. Try change of climate, e. g., going from Canada to some place south, the favorite place being California. Many found, through clinical observation, that the pressure reducers, especially the nitrites which lower pressure by vasodilatation, do more harm than good. It is also thought the proper plan is to treat the serious condition itself and not one of its symptoms. If we accept this view, we can simplify the therapeutics by eliminating No. 1, then we shall not need No. 2.

Probably most practitioners now agree that No. 3 contains the most important if not the essential features. What about California? I should eliminate it entirely. The climate of a quiet comfortable home where the patient is surrounded by those she loves, is the best I have discovered.

One of my patients, a woman aged sixty-two years, has had arteriosclerosis for eight years (perhaps more). The blood pressure, from 1910 to 1915, averaged 230 to 240. Up to 1912 she took at various times such medicine as mannitol nitrite and erythrol tetranitrate. Neither did any good. I thought each did actual harm. She has had nothing of that sort for the last four years. She avoids as far as possible all the causes of high pressure. She takes cascara, rhubarb, salines, phenolphthalein, with occasional doses of calomel or blue pill. Her favorite laxative is a pill made up of blue mass and compound rhubarb; a pill of two and a half grains each is taken at bedtime on three consecutive nights.

For some years it was supposed that by the serum diagnosis (Wassermann reaction) in the later stages of syphilis, whether active or latent, the disease could be detected. A little more than a year ago a patient was in the Toronto General Hospital. For some reason which I do not know he was subjected to the Wassermann. The laboratory finding was positive. After an interval a second positive was declared. The patient, a married man with a family, was then told that he had latent syphilis. He was much astonished and greatly worried. Now it happens that we have recently been able to tell him that he has never had any symptoms of syphilis, and this statement has given him unbounded comfort. Even at that time it was recognized in many hospitals and laboratories that the Wassermann reaction was "merely an auxiliary to the diagnosis of syphilis, which must ultimately stand or fall by the clinical examination" (Fönss). Freudenthal could have told them some time before that he sent specimens of the same blood to four institutes in Berlin; in two the reaction was found to be negative, in the third it was doubtful, and in the fourth it was markedly positive.

It is unfortunate that the clinician and the laboratory men do not work these cases out together with the hope that they may finally agree. Although there may be some doubt about the significance of certain findings, it seems to have been established that the reaction cannot be positive in the absence of syphilis unless through technical error. On account of the number of such errors, especially in Berlin, this work has been for some time carried out exclusively in the State Institute in Holland.

A brief report will now be given of one of our ordinary every day patients with symptoms easily discoverable by ordinary methods. A girl, aged fifteen years, was brought to me by her father a few weeks ago. An appendicectomy had been performed by an excellent surgeon in Montreal more than a year before with apparently good immediate results, allowing her to be removed from the hospital to her home in two weeks. For months, however, she did not appear to be well, and numerous and varied laboratory investigations had been made. After a time she got fairly well, and was sent to one of our best boarding schools in Toronto. Reports as to her physical condition not being favorable, the father came to Toronto and placed her under my care. He told me she was run down, got tired easily, and suffered from headache and constipation. I found out from the patient herself that she also had

disorders of menstruation, and one other symptom to which she attached importance, viz., heartburn, after every meal. The father told me that the laboratory findings showed "thin blood," but nothing else "very bad." For anemia she was getting iron tonics and plenty of good nourishing food. He wished me to look after the meals, and see that she got plenty of hot meat at least twice a day. I went to the school a couple of days after and found that she was getting three heavy meals a day, and in addition three full glasses of milk, and chocolate and cocoa at various periods of the day. The bowels had not been moved by a laxative mixture which I gave her, when I first saw her. The combination of meat and milk is particularly vicious.

Here was a charming, handsome, strong girl with good physique with an appetite which caused her to eat more food than she could properly assimilate, and her whole system was being poisoned because of defective elimination. It was just a plain old fashioned case with clinical manifestations sufficiently clear to indicate proper simple treatment. There was no albuminuria or glycosuria in any form. A restricted diet was ordered, and after some days the bowels were properly evacuated. After this she felt better, but more hungry than ever; and now the big fight has begun. She demands the hot meat twice a day, and she gets it, although she is submitting to most of the other restrictions. In this case, as so often happens, the doctor and the indulgent, kind woman in charge, have opposed to them the strong wills of a forceful father and a determined girl. Who will win in this case, I do not know, but if we fail the girl will suffer and come into mature womanhood crippled and perhaps broken down. Surely the so called older methods of diagnosis and treatment in this case are the all important ones, although great assistance may be derived from careful laboratory investigations in the future.

Is it true, as many of our best physicians fear, that the tendency for the young practitioners who have received admirable courses in our well equipped colleges is to neglect the human side, and to treat the disease instead of the patient, forgetting or overlooking the important fact that the latter always is a personality which should be carefully considered? Are we losing the kindly sympathy which was formerly of so much assistance in the treatment of our patient? Are we becoming mere mechanics, neglecting "the higher and more intellectual means of drawing conclusions by inductive reasoning?" (Shepherd.) Are the men who are trying to divorce science from practice, to exalt the laboratory investigators and belittle the clinicians, working in the interests of our profession or of suffering humanity? We are inclined to answer—No, and at the same time to express the opinion that it would be better to work loyally together, and thus be in a position to put forward our strongest and united efforts to do the best we can for the patients placed under our care. In doing so we may think it well to go back to Hippocrates and carry out his advice by paying very great attention to acute observation and careful interpretation of symptoms.

30 Gerrard Street, East Toronto.

AN ANALYSIS OF CERTAIN NEUROTIC SYMPTOMS.*

By C. P. Oberndorf, M. D.,
New York,
Clinical Instructor, Neurology, Cornell Medical School; Adjunct Visiting Neurologist, Montefiore Home.

In one of his initial lectures in neurology delivered before the seniors at Cornell Medical School some ten years ago, Dr. C. L. Dana announced that the textbooks for the course would be three: one by Dr. Conan Doyle called *Sherlock Holmes;* another by W. M. Thackeray entitled *Vanity Fair,* and a third by C. L. Dana, *A Textbook in Neurology.* To this he whimsically added, "You needn't bother about the last, but be sure to read the first two."

Of course, the inference drawn was that *Sherlock Holmes* had been recommended for its exposition of deduction. However, it was not until recently when at the suggestion of a patient I read *Pendennis,* that I was granted a fuller appreciation of Thackeray's subtlety of character analysis and his understanding of many of the mechanisms later emphasized by the psychanalytic school in the elucidation of those queer turns of thought and action to which all of us are subject from time to time. And so, forsaking the more classical neurology as exemplified by textbooks and principles, let me quote from *Pendennis* two passages pertinent to the theme of this paper.

In recording Pendennis's (Chapter 24) love affair with Laura, Thackeray describes Mrs. Pendennis, Arthur Pendennis's mother, as watching it with "that anxiety with which brooding women watch over their sons' affections—and in acknowledging which, I have no doubt there is *sexual jealousy* on the mother's part and a secret pang."

In the same chapter Laura is described as becoming jealous when her dearest friend Blanche showed her some love poems written to Blanche by Pendennis, with whom Laura herself was infatuated. At the time Laura had listened in silence to the poems, and after she and Blanche left the room, paused, and looking her friend kindly and frankly in the face, kissed her with a sisterly warmth. But later in the day, Laura quarreled with Blanche, and in relating the latter incident to Mrs. Pendennis, omitted mention of her jealousy, and attributed her indignation to the fact that Blanche had wantonly mistreated one of the maid servants. Here Thackeray again comments, "but Miss Laura did not tell Mrs. Pendennis, perhaps *did not acknowledge to herself* what had been the cause of the altercation."

In these passages Thackeray has pointed out two mental processes which are usually unconscious to us, but which are nevertheless prevalent and powerful in their influence on our actions. The last quoted mechanism, that of displacement, by which we ascribe an affect to one act which in reality belongs to another, or substitute one object for another, or allow part of an object or one of a certain class to represent the whole, is common enough, but rarely entirely acknowledged. The case to fol-

*Read, in part, before the Bellevue Alumni Society.; in part before the Section on Neurology and Psychiatry, New York Academy of Medicine.

low, while exposing a pathological relationship between mother and son, such as Thackeray intimates, illustrates far more convincingly than the examples quoted from *Pendennis*, at least so I hope, displacements based on purely individualistic thought associations and resulting in unusual somatic manifestations.

History. The patient, to whom I shall refer as Robert C., or Bobby, was born as the first child of comfortably situated, middle class family, in 1885. The father, who had emigrated from Germany to the United States as a boy, was a shrinking, thoroughly reliable, extremely conscientious young man, who, by virtue of these qualities at the time of his marriage, gave every promise of the achievement of a commercial success—which has since been realized. The mother, who had been a school teacher, a prim person with high regard for the conventionalities of life, was no longer very young at the time of her marriage.

It is difficult to estimate just how much love existed between this reserved couple, but it is certain that the woman devoted great attention to the physical comforts of her husband, who rarely remitted his immersion in work. Notwithstanding the increasing prominence which the father's success in the commercial world had brought to the family's name, they remained isolated, with few friends and limited connections. During the last years just preceding her death, the wife, then about fifty-five years old, permitted long cherished desires for wordly recognition to come to the surface, with attempts at the deferred gratification of her social aspirations.

Whether the father ever felt affection for the patient is hard to determine—his prime interests, which were concentrated in his allegiance to a large corporation, left him little time for association with his son. Primarily a methodical man, almost a recluse, the father developed very precise ideas about morals and men. He was punctilious in his habits and dress, subservient in his relations to his superiors, and though reactionarily liberal in religious matters, was puritanical in his liberalism.

For seven years, during which Robert remained an only child, incessant attention was lavished upon him by the fond mother. That his associates might be only well bred children, at six years of age he entered one of the best private schools, where he continued until he had prepared for college. In his studies he progressed with the average, neither extraordinarily proficient nor markedly defective, though at the age of fourteen years he failed of promotion.

Inasmuch as conventionality decreed it a proper procedure for the complete preparation of a young man for life, the family decided that he go away for his college course and selected one well known for its high educational rating—let us say Johns Hopkins. At the university, as at his school, his external life passed in a quiet, unostentatious way. He made few friends, had no vices, passed his examinations when the time came—to his parents a satisfactory record.

A peculiar handicap (a blurring vision), a neurotic symptom upon which we shall dwell later, prevented all participation in the sports of youth. The only activity outside of university work while at Hopkins consisted in several investigations of street cleaning problems and garbage disposal undertaken voluntarily for a civic organization in Baltimore. After his graduation from the university he engaged in mercantile enterprises in this city.

While it will be seen that so far as Robert's intellectual welfare was concerned, every precaution was taken, the sexual aspect of his development received scant attention. In the household propriety developed to such an extent of prudery that any reference to matters of sex was considered improper, and the inevitable little occurrences of a sexual nature the patient was taught to consider as funny. Both parents would pass off such episodes with a constrained laughter which the patient suspects was intended to conceal their own embarrassment. To be naughty was to be funny.

One of the jests which never failed to elicit a smile in the family circle was the exhibiting of a photograph, taken at the age of six years, which showed where the patient had urinated while standing for his picture. At an early age Bobby conceived a certain amount of pleasure from the attention bestowed upon the clever little perpetrator of so funny a performance. This attitude remained with him until at college he was rudely awakened to the conception that to be naughty carried with it no claims to humor in other families.[1]

Notwithstanding the artificial attempts of the parents to ignore sex, the patient's innate libidinous forces revealed themselves early, and masturbation, begun at twelve years, assumed the unusual procedure of lathering the genitals while he was in the bath.

The patient's activities in the bath room gradually embraced an elaborate scope in connection with urination and defecation. Finally masturbation could be produced only after prolonged rhythmical lathering of the genitals. It may be noted here that the patient usually took his bath just before supper and that not infrequently received reprimands for his tardiness in reaching the table. Some form of active masturbatory indulgence continued up to twenty-four years, but he had never indulged in intercourse.

Symptoms. The patient consulted me primarily for a feeling of drowsiness which would come over him in the barber's chair (association of lathering) and overwhelmed him at other inopportune moments, notably while traveling in railroad trains. It soon developed that he also suffered from a host of other neurotic manifestations, of which I shall mention only those to be discussed in this paper. They included, aside from the drowsy periods, a blurring of vision, for which he had been long treated by opthalmologists, inability to cross a street or ride in an auto-

[1]Freud explains the smile as resulting from energy coming from the relaxation of the hold of a censoring thought over a suppressed wish. Holt, on the other hand, thinks it due to an "overflow of energy from the hitherto suppressed wish into the facial muscles. . . ." "If the suppressed wish is sufficiently relieved by one discharge" (of smiling or laughter), "the joke is forgotten and the smile fades. If the wish has a larger store of pent up energy, the joke lingers in the mind and the smile on the face: it may be for days." (E. B. Holt, *The Freudian Wish and Its Place in Ethics*, 1915, page 2[illegible]) Undoubtedly in the case of the patient, the mechanism corresponds more nearly to the mechanism advanced by Holt. The repeated response in smiling at the same joke or type of joke—for as a rule after hearing a joke once or twice it grows stale, and we no longer respond—indicates, to my mind, the extent and persistence of suppression by the censor in the minds of Robert's parents of their natural sexual interests.

mobile, and a feeling of uncertainty in walking which he had attempted to rectify by wearing rubbers almost constantly.

Avoiding the digressions with which it is customary to approach a delicate subject, let us enter into the consideration of the origin of the dreamy states.

The drowsy states.—Though no sense of guilt; on the contrary, a playful spirit (to be naughty is to be funny) accompanied masturbation in the early stage, presently an inevitable conflict arose in the patient's mind between the parental attitude on moral matters, strengthened by terrifying information gleaned from external sources and his increasing adolescent libido.

Shortly after beginning masturbation, nocturnal emissions following erotic dreams often troubled the patient. At fourteen years, however, the family physician, a leading consultant of this city, to whom he was taken for stomach trouble, inquired of the boy whether he masturbated, at which he promptly and stoutly lied. When this query was followed by another in a milder tone as to nocturnal emissions the patient deeming this less reprehensible, confessed, and to his astonishment found that the physician seemed to countenance the circumstance as being quite natural.

After receiving medical approbation, so to speak, for the pollutions, the patient resorted to the expedient of consciously attempting to induce sleep in order to defer erotic gratification until it should find its egress in the dreams accompanying nocturnal emissions and thus relieve himself of responsibility for their occurrence. This compromise not proving satisfactory, on account of difficulty encountered in falling asleep, he substituted a voluntary dreamy, half sleep stage, during which he indulged in fancies of contact and exhibition which might or might not be allowed to culminate in ejaculation.

During the conflict which always preceded masturbation he would usually think of his mother, with the idea that the thought of her purity would enable him to banish his own erotic cravings, but when unsuccessful in curbing the impulse he would intentionally direct his thoughts to a person of inferior social scale—usually a servant girl. Very probably, the thought of his mother, the object of his early infantile sexual fixation—which will become more apparent in connection with the vision symptoms—in itself unconsciously furnished an erotic stimulus, which very natural resistances, engendered through a high ethical sense, forced him to displace into a lower social plane.

Not until he entered college did the drowsy periods occur without conscious knowledge on the patient's part of their connection with sexual activities. Invariably at 3 p. m. he noticed a feeling of drowsiness which he would fight for ten minutes, but he grew more and more sleepy. This was succeeded by a feeling of absolute absence of any mentation—a mental vacuum—for five minutes, from which he would awake with a sensation of general muscular shrinking and a start, which he always attempted to conceal from his classmates. With the exception of slight nausea after such an attack, the patient could continue his classroom work without the slightest impairment of intellectual discernment.

In very recent years, when he had brought himself to fondle the young woman to whom he is engaged, he experienced the same fight and transient drowsiness at the outset, but when ejaculation occurred as a result of his spooning there was no mental vacuum or muscular shrinking of the body.

While it is impossible to adduce many other points on which the following interpretation is based, it would seem that the fight represented the struggle against masturbation; the drowsiness stood for the fancies, the mental vacuum corresponded quite closely to the emission completed, and the feeling of muscular contraction on awakening, to the contraction after ejaculation.

Masturbation had been practically discontinued for over three years, but the drowsy states had increased alarmingly, though their connection with his former habit, as being another form of the same thing, never even occurred to the patient, until an accompanying explosive feeling in the testes caused him to think that his mental lapses might have a sexual significance.

From its analytical aspect it is of some import that shortly after his mother's death, he became engaged to a young woman decidedly his social inferior—a barber's daughter (association of lathering and adjustment of intolerable sexual longings for the mother through debasement of the ideal).

Those who regard with skepticism the interpretation of some of the more obscure symbolic interpretations of psychanalysts may perhaps in the light of the preceding data be inclined to attach a sexual interpretation to the following complaint: Whenever the patient squeezed a paste (such as tooth paste or cold cream) from a collapsible tinfoil tube he suffered from a darting pain in the testes.

Ocular and locomotor disturbance.—A conjoint consideration of the blurring vision previously mentioned and of the difficulty in locomotion is desirable, as the symptoms are so closely connected psychologically.

The eyes.—The ocular symptoms have assumed a predominance among Bob's many difficulties. In this connection it must be recorded with some stress that among his very earliest recollections is his childish curiosity in loitering about the room while his mother disrobed. Although the mother, who was particularly rigorous in such matters, would remove only her waist in his presence, his interest in the procedure developed so obviously that she reprimanded him severely with the threat that he would become blind if he looked at her—a warning which so impressed itself upon the plastic mind of the child as subsequently to form a definite and universal standard for his judgment of morality.

Further confirmation of the responsibility of the eyes as indicators of moral worth occurred at the momentous time of his departure for college, when the affected mother's final admonition as to his conduct after he had passed from her protecting custody, found expression in the hope that he would be able "to look her in the eyes," when he returned.

It was not until he began masturbation that any affection of the eyes was noticed, but then he per-

ceived an inaccuracy in focusing, which the opthalmologist, to whom he was referred by his family physician, diagnosed as a muscular weakness and prescribed glasses. Although the patient wore glasses from his fourteenth to his twenty-sixth year and underwent periodical atropine treatments for his vision, his physician remarked when he revisited him about four years ago, because the glasses no longer seemed suited to his vision, "it may be the eyes and it may be the brain." New glasses, however, were ordered.

At the time that Robert C. originally consulted the ophthalmologist, he was devoting much attention to the examination of the size of his pupils, which he believed became widened and strained after his masturbatory practices. The conviction settled upon him that the eyes were "getting even" with the testicles or more bluntly expressed, "because the testicles made trouble for the eyes, the eyes had made trouble for the testicles."

Thus, to the widened pupil he ascribed his difficulty in focusing, which, in turn, prevented his participation in any game where a quick movement of the eye is required.

As years progressed he interpreted the troubles with his eyes as being a conflict of direction, trying to fix the eyes forward and sidewise at the same time. As a supplementary explanation of his inaptitude in running arose the feeling that he "did not like to go, without seeing where he was going"; that is, he had to glance sidewise before going ahead.

Among other idiosyncrasies with the patient's eyes is the weakness of his left eye only and his ability to wink only with the left eye. Furthermore, it is impossible for him to close the right eye and simultaneously keep the left one open. There is, too, an almost conscious, semivolitional habit of withdrawing his eyes whenever anything is distasteful to him and he becomes distinctly aware of his inability to see. Often, on riding on street cars, for some inexplicable reason, he must close his eyes.

Flashes of light from street lamps have been a source of annoyance to him, because his attention was arrested too long upon them, especially the red and green lamps on the port and starboard sides of a ship. His method of remembering the position of these ship lights is significant.

At the time when sexual activities were engrossing so much of his thought, the red light district investigations, which like religious revivals of the Billy Sunday type flare up spasmodically as consolation reactions against our shortcomings, filled the newspapers with overt allusions as to the immoral symbolism of the red light. The red light represented wickedness.

Transferring this symbolism to the lights of the ship, he argued that right is right, while left is not. The red light is not right and the red light is on the left side of the ship, and the green on the right side. Restating this, the red, which is left, is not right, but wrong, wicked, naughty.[2]

[2]The common association of red with wrongness finds unconscious expression in many phases of every day life, e. g. The following squib taken from the daily "column" of one of the local papers: "Sir—Red lights mean evil; white lights, good." Oui! Witness the elevator: the white takes you up, the red drops you down."

So, too, the electric sign announcing the play, *The Unchastened Woman*, has the words "the" and "woman" in white lights, while "unchastened" blazes forth in red.

The wrongness of the left, in its deviation from moral rectitude, became further accentuated by the circumstance that he is congenitally left handed, which was regarded by his parents as an abnormality which could only be corrected by constant reprovals. Moreover, he employed his left hand in performing what to his mind constituted his greatest moral transgression.

The feet.—Disregarding for a moment the eye symptoms, I will consider the difficulties which the patient experienced in locomotion, especially the inability to coordinate eyes and feet. When Robert C. emerged from kilts to trousers, the mother noticed that the left foot turned inward when he walked, and to adjust this defect, often scolded him. In view of the incessant censure directed by the otherwise indulgent mother toward the left foot, coming as it did at the time of the reprimands about the blindness (and also the left hand), the patient began to regard the physical peculiarity as a grave defect and his foot as an offender against decorum and propriety, which, like his eyes, would lead him into trouble. Such an inference is quite logical to the child's mind, which cannot judge values with the same nicety as that of the adult's, and which is apt to regard any act arousing the displeasure of authority on the same plane and as of equivalent moral value.

A new and decisive element was introduced into the patient's mental fabric by the feet sinning in another and more direct connection. When at the age of twelve years, his mind was immersed in sexual problems, he received an invitation to play croquet with the fourteen year old daughter of a neighbor, but on going to the house the girl's mother informed him that her daughter would be unable to receive him on account of an injury to her ankle. When his own mother inquired the reason for his immediate return home, he explained that the party had been postponed because the girl had sprained her ankle. Thereupon his mother insinuated that the injured ankle constituted a euphemism for the real cause of the postponement—namely, the girl's menstrual period.

Thereafter "ankles" assumed the same significance to the patient that the term "unwell" does when used in its restricted medical sense as applied to the female. Like many other idiosyncrasies in the narrow life of Robert's family, "ankles" passed into a secret household idiom for menstruation. Thus, the mother, who, in her devotion, corresponded daily with her son while he attended college, would from time to time, in relating household incidents, say, "I have not been quite well for a few days—nothing serious ('ankles')," or "I have been under the weather ('ankles')."

A further extension of the connection of ankles with menstruation and sex resulted through the unusual significance attributed to menstruation itself. Having ascertained from several sources that menstruation consisted of a bloody discharge, he inferred it to be the "issue of the blood" of which he had read in the Bible, appearing periodically. About the same time, with the augmentation of his physiological erudition, he learned that semen was formed from blood, and, combining the two bits of information, concluded that the ejaculation (issue of se-

men), i. e. (blood), and menstruation constituted identical processes occurring in opposite sexes.

The patient's ejaculations, phraseologically and psychologically speaking, became his "ankles," and as the former invariably resulted from some form of forbidden, remorse engendering, sex activity, they (the ejaculations, ankles) were decidedly culpable. It certainly possessed every advantage for the youthful judge to prefer to inculpate his sinning ankles, which might be openly condemned with every propriety, and, on the other hand, might be more amenable to discipline than the irrepressible sex activities.

With these brief facts at our disposal, let us return to the basis of moral values at which we have already hinted. Three distinct forms of misconduct were impressed upon Robert C. during his early childhood—the eyes, the left foot, and any form of sex indulgence, all of which subsequently became psychologically closely interwoven, but each of which had been originally considered ethically reprehensible. Although independently regarded, each was culpable, masturbation unquestionably twinged his conscience most poignantly, and this, as previously outlined, he attempted to replace by a compromise dream state.

It has been aptly said that compensation is a thing which does not quite compensate, and in this instance, the substitution of dream states, could not completely indemnify Robert's conscience for all the naughtiness of sex activity. So analogous to the mother's delicacy in referring to her daughter's menstrual period as a case of sprained ankle, it carried with it less odium for the patient unconsciously to displace the blame of his own weaknesses to his delinquent eye and impeachable left foot.

Analysis. If we grant that the assumption that displacements, so common in daily life, may take place unconsciously, many of the patient's symptoms are ready for elucidation. In his earlier childhood, when he first attended dancing school, he was conscious of his body, but not of his feet, which at this stage gave him no trouble. At this time the consciousness of the genitals was directed to the torso (the whole representing a part), and in later years this was further transplanted to the psychically associated feet and eyes, which resulted in such stumbling, reeling, and dizziness that he gave up dancing.

According to the patient, his troubles in locomotion are attributable to a tendency on the part of both his feet and eyes to remain anchored. Undoubtedly he describes accurately what he feels, but sensation of ocular fixation is an overcompensation on the patient's part to counteract their tendency to rove. In other words, if his eyes and feet are both fixed, they cannot slip or go in a wrong direction. Thus, the wearing of rubbers on dry days reinforces the tendency to make his progress sure and prevents his foot (ankles) from slipping—that is, tends to preserve his psychically associated sexual and moral equilibrium. Biblically speaking, if his eyes and feet were fixed, it would be a simple matter for him to progress in the proverbial straight and narrow path, from which he possessed so strong an inclination to deviate.

The "left" factor. In crossing a street filled with conveyances, he encounters difficulty because he must fix his eyes on each separate vehicle, but when he has succeeded in traversing one half of the street, he feels himself quite safe. The automobiles in our avenues, as those of us who through necessity or choice venture afoot fully realize, afford a valid source for caution, but, after glancing quickly about, we estimate distances and proceed. Robert C., however, when in any danger, must fix his eyes to prevent their slipping until the danger is passed, for in the presence of danger—immorality—his eyes must not slip (sin), and so he cannot withdraw them from the individual vehicle sufficiently promptly to avoid the next one.

It is striking that in crossing a street like upper Broadway, where an esplanade divides the broad roadway into two practically distinct avenues of traffic of the same width and equally busy, the patient is disturbed in crossing the side where traffic approaches from the left, but feels secure when the vehicles bear down upon him from the right. Both this circumstance and the absence of fear when half way across an ordinary street, is accounted for by the fact that, in America, at least, all vehicles approach from the left, the patient's wicked, naughty, or danger side, and after he has progressed half way he feels relieved, inasmuch as from the right he stands in no jeopardy.

During his visit to London, some four years ago, he experienced, as he expresses it, a "terrible dilemma," for in England traffic keeps to the left. It puzzled him that he was able to start boldly across a street, but, before reaching the opposite sidewalk, fell into a state of panic and trembling. In the light of the analysis this mystery is dispersed, for of course in England his zone of danger was only reached when he had got beyond the middle of the road where traffic began to approach from the left. He successfully avoided this symptom in London, however, by an extravagant use of taxicabs.

The closing of his eyes when in street cars and withdrawing them when anything is distasteful is likewise clear. What Robert C. seeks to avoid is something undoubtedly distasteful to his conscious appreciation, but which probably furnishes him pleasure unconsciously. Upon entering a car his eyes are apt to immediately range down the seats along the aisle in an attempt to determine the height of women's busts, which condition possesses a particular significance for him. High busted women are all intelligent. The origin of this interpretation may be partially traced to the unusually high bust he attributes to his mother (school teacher), who to his mind represented superior intellect, amplified by an inference from the wood cut illustrations in the school geography. In these pictures he noticed that very low busts are characteristic of Hottentot and Ethiopian women savages. His childish conception led to the conclusion that the lower in the scale of civilization a woman, the lower her bust, and, conversely, high busted women represent the intellectual. Now the patient wishes to regale his displaced desires for the intellectual, i. e., the high bust (like his mother's), but as such an action conflicts with his unconsciously elaborated protection against looking,

in conformance with the maternal admonitions,[3] he must close his eyes in self defense.

The inability to wink with the right eye, notwithstanding a perfect freedom to do so with the left, seems referable to the naughtiness associated with winking, a function which might perfectly harmoniously be relegated to the offending left eye. So, too, the inability to keep the left eye open when the right eye is closed, seems due to the psychological guardianship which the well behaved right eye exerts over its mischievous, sinister companion, which might be in greater liability of slipping (sinning) if its righteous associate should even temporarily be remiss in its duty.

The function of the glasses now becomes somewhat clearer—the blurring represents a punishment to the eyes psychologically for their misdemeanor in wandering in forbidden fields, and forms a compromise of his mother's warning of punitive blindness and his desire to peek, for he might look, but would not see plainly, not everything, only blurred, half blinded. Thus, the glasses, while ostensibly remedying the defect in permitting him to see more distinctly, at the same time shielded his own eyes from the penetratively detecting gaze of others. Furthermore, the glasses, like the rubbers, yielded a certain security, forcing him to focus straight ahead, acting not dissimilarly from the blinders of a horse, by preventing him through a sidewise glance from running into danger.

As an example of psychophysical displacement, particularly pertinent in this case, I would mention that in the early part of the psychanalytic treatment the patient suffered from noticeable restlessness and frequently winced while standing (he could not sit for a long while in a chair). Subsequently he confessed to me that at every mention of sexual topics he experienced a distinct sensation of having received a stinging blow between the eyes.

Riding symptoms. Another symptom, that of allowing his ankle to slip whenever a horse fell or stumbled in the street, naturally implies some psychological association existing between the patient and the horse or something represented by the horse. In tracing its origin I found its genesis to be a substantiation of one of the most vehemently criticised Freudian theories.

H. von Hug-Helmuth, in *Seelenleben des Kindes,* closely following the tenets of the psychanalytic school, states that possibly the earliest and greatest part of the knowledge of sound and word acquired by the very young child has its origin in anal and urethral eroticism. Whether we accept or reject this apparently extreme theory, it is maintained by the analytic school with more obvious and more readily demonstrable basis, that when a child arrives at the stage of echolalia (babbling) during which it constantly repeats the same sound over and over again, often accompanying it with rhythmical muscular bodily movements, the infant has become possessed of a new and pleasurable stimulus which forms a basis for muscle erotism.

In later years, muscular erotism finds expression in climbing, sliding, and rocking. So long as the child remains the passive object in the swinging and rocking, it receives, in addition to the purely physical pleasure from the regular motion, a certain degree of gratification from the attention which even the very young child realizes is bestowed upon it by the person rocking or doing the swinging.

Among our patient's earliest recollections is the fond memory of the constant practice of riding his mother's or aunt's knee to the rhythmical swing of a well known German nursery rhyme, frequently used in the household as a lullaby, which may be rendered into English almost verbatim:

Hop—Hop—Hop,
Horsie runs gallop,
Over stick and over stone,
Horsie breaks his left leg bone,
Hop, hop, hop, hop—
Horsie runs gallop.

Another favorite which proved very effective in lulling him to sleep was Schubert's well known *Erl King,* which his mother sang with rhythmical chant and a sonorous crescendo. The opening stanza of the *Erl King,* it may be recalled, begins "Who rides so late through night and wind?"

The utilization of rhythmical motion as a soothing pleasure finds further exemplification in the cure of stomach aches which Robert feigned whenever he had "something on his conscience" (retributory displacement for masturbation before dinner time) which he believed did not quite conform with the ethical standards of his parents. The treatment for such stomach attacks, in addition to the medication which he tolerated, included the solace of being rocked and cuddled to sleep by his mother. These attacks, so fraught with comfort, continued until he became ten years old, when riding and rocking ceased.

On at least one occasion, at about the age of nine years, when the gastric pains appeared intractable to the ordinary rocking, he was permitted to revert, in addition to the rocking, to an even more elementary form of pacifying a refractory child—namely, suckling at the mother's breast.

If we consider suckling at this age to be a manifestation of active erotism (which does not appear to me to be far fetched), the lullaby and its accompanying rocking and suckling no longer remains an unconscious source of lust to Robert C., but furnishes a transition to the consciously sexual.

As he grew older, approximately at ten years, through the application of the terminology of some farm yard breeding talk which he had overheard—"the male mounting the female"—he began to conceive of coitus as a purely riding motion. In other words, riding thus became further identified with the sexual act, in which the male is represented as the rider and the female the thing ridden. So firm-

[3] The new art of the photo play utilizes and exemplifies graphically the mechanism operative in the mind in such an instance. The possibility of recalling to the mind of the spectator the vital influence of some scene long enacted upon some event years subsequent is accomplished by the "cut back." To impress the interrelationship of effect and cause, the latter of which may have momentarily escaped the spectator, at a critical moment the earlier scene is flashed before his view, obliterating time and juxtaposing the early influence with the late effect. Unconsciously the mind does this, drawing on its limitless fund of scene impressions of varying dynamic force, which it can bring to consciousness "in a flash."

The film producers have also discovered how an isolated feature may serve as the keynote to the entire plot—a particularly long arm, slender fingers, a leer in the facial expression, a wistful smile at saying farewell—and the picture is narrowed down to emphasize the potency of such a single aspect. In the mental drama which is under analysis there is an analogous constant psychological use of the cut back and a narrowing of the field of observation to the inevitable eye warning.

ly had this conception been impressed that at the time of the analysis he believed this to be the position of the bodies in normal copulation.

It is notable that at fourteen years, after slipping from his horse without injury, he discontinued riding his pony and never resumed this form of exercise.

The extension of this aversion to motion, as exemplified in the more explicitly erotic horseback riding, into other types of movement includes automobiling and motor boating, and we find a strikingly plausible connection between these different forms of motion through bicycle riding which enjoyed great vogue during Bob's adolescent period. As he correctly observes, the bicycle (or machine, as he prefers to designate it) is almost the only machine in which gender comes into consideration, as here we have the man's bicycle and the woman's bicycle which are distinguished by the fact that the man's machine (bicycle) has a middle bar which the woman's machine lacks. Moreover, it is entirely feasible and conventionally proper for a man to ride a woman's machine (bicycle) while the converse does not hold good.

In this connection he recalled an anecdote which puzzled him when he heard it as a child, namely, two machines (bicycles) were stored away in a barn for the winter and the next spring they found with them a little velocipede.

Other investigators on the subject of fear of locomotion have found a close association between repressed desire for rhythmical motion and the fear of moving. Abraham[1] especially calls attention to the point that in cases in which he has been able to make an analysis, the patient possessed a constitutionally exaggerated pleasure in motion which had been artificially fostered. Although I had not read Abraham's report at the time that this analysis was undertaken (1913-1914), I arrived at the conclusion that the unsuccessful attempt at the repression of the patient's penchant for rhythmical motion—in this case so palpably associated with masturbation and coitus fancies—led to the development of a protective neurotic fear against all form of motion.

Applying this line of reasoning to Robert's aversion to riding, the explanation resolves itself into an attempt to overcome any form of the movement associated with rhythm (sex) and the conversion of the primary positive desire into its negative form —i. e., an exaggerated disgust for motion as exemplified by riding. This attempt at conversion, like most endeavors of this kind, did not completely suffice, for the identification of the rider and the object ridden (horse) had become psychologically inseparable. Therefore if the horse stumbled (sin), the rider would slip (sin-indulge in sex activity) and the patient's act of slipping at such times becomes, in this light, the mental equivalent of sexual indulgence.

Robert C., after graduation from Hopkins, completed his education by a trip abroad, during which time he toured extensively in an automobile (or machine, as he was wont to call it). About six years ago, however, after skidding (slipping) he was compelled to give up driving his own car and since then he has felt uncomfortable and nervous whenever he was compelled to ride in an auto.

Robert's aversion to automobiling developed coincidently with his cessation of masturbation. In other words, he could no longer tolerate the association of being occupied with a machine and after allowing his auto (machine) to skid (slip) in public, he felt impelled, from its unconscious association, to prevent the repetition of such an occurrence by relinquishing driving altogether.

In the choice of synonyms for the automobile the patient states that when the automobile is mentioned in the home circle he refers to it as the "car"; during casual conversation with friends or acquaintances it is the "motor"; but when he lapses into casuistic speech and is off his guard, he has noticed that it invariably becomes the "machine."

In the transmutation of what is ordinarily a pleasure into a source of torture, the automobile did not stand alone, for the patient remarked one day, "I cannot get any fun out of my motor boat—I listen to every explosion of the engine—thump, thump, thump—it's a nasty responsibility to run a motor boat when you've only got one cylinder." Some time previously he had complained that he was apt to be troubled by constant erections when in a motor boat, but at the time I had not realized its import.

Supplementary to his irritation at the regular explosion in the puffing of the engine was a fear of striking a rock as he cruised along. Inasmuch as the fear was expressed even when the boat moved smoothly along in deep water, he became the laughing stock of his own guests. As a matter of fact, the fear of striking a rock was really a sort of secondary subterfuge in expressing a more primary and essential fear of losing control of his engine. In his own explanatory phraseology he "would hate to lose control of the engine and run on a rock and come to a sudden stop."

If we pause to reflect, it will be found that the motor boat contains all the disturbing elements mentioned separately in connection with horseback and automobile riding—motion, rocking, and a machine (engine), with the additional element of vibration.

It has already been established that a machine (engine) signified unconsciously to the patient the sexual organs, also that any form of rhythmical movements had become psychologically associated with sexual practices. Masturbation, according to the patient, consisted not only of a regular, modulated lathering movement, but also of a vibratory sensation which began with the erection and continued almost up to the time of seminal discharge. He noticed that just immediately preceding ejaculation there occurred a distinct pause, when all vibration ceased and he realized that when this stage had been reached, he could no longer prevent the discharge. His annoyance at the cessation of vibration impelled the patient to make determined efforts to induce ejaculation before vibration should cease—in other words he disliked being made conscious of his inability to continue control.

If we translate these practices with his own genitals (machine) into the fear connected with

[1] Karl Abraham, *Zeitschrift für Aertzliche Psycho-Analyse*, ii. 3.

motor boating, it would seem that annoyance at the rhythmical explosions of the engine and the vibration is an over compensated disgust for his sexual vibration and discharge, displaced into a more favorable setting.

The fear of running on to a rock—stopping suddenly—is the equivalent of a protection against the sudden cessation of vibration, that is, loss of control, which he tried to prevent in masturbation. Unconsciously the combination of the thought complexes connected with motion, rocking, and vibration, yielded sufficient stimulation to cause the inexplicable erections while in the boat. He rather suggestively amplified in an attempt at extenuation of his fear in boating that "the engine in his boat was a one cylinder affair and you'd be absolutely helpless if anything should happen to that one cylinder."

Perhaps a hint of the reason for the patient's unyielding opposition to his mother's fond hope that he study engineering may also be found in this compensatory dislike for machines.

CONCLUSION.

In following the somewhat involved, apparently speculative, and, I fear, hazy exposition set forth in this paper, the reader may perhaps have transiently lost sight of the fact that we were dealing with a sick person whose symptoms had been actively treated by competent physicians in approved ways. He is no longer under treatment and is as well as the ordinary person would be who is confronted by a serious actual problem which must still be solved, for his father, who furnished him with capital which he invested in a wine importing business which has been destroyed by the European war, irrevocably opposes his marriage to the barber's daughter—to be sure not on psychological, but purely on social and religious grounds. Such a dilemma might be sufficient to disturb a person of less complex mental constitution.

On the other hand, he came to me complaining of the following purely neurotic symptoms: Drowsy states and mental vacuum, the visual defect and the disturbance in locomotion. When he began to comprehend the substitutive nature of the drowsy states and their significance became conscious, he was freed from this source of vexation, so that he can now recline with normal comfort, even in a barber's chair, and travel unhampered on long railroad journeys. Further, after wearing glasses for sixteen years, he finds his vision so clear that their use is unnecessary.

One sleety night after about four months' treatment, he forgot his rubbers on leaving the office and has since discarded them except for the normal use, and although in his present occupation he is compelled to do much outside work as city representative of his firm, he crosses Fifth Avenue of an afternoon in normal safety or jeopardy—as you choose. Last summer he toured extensively in his "machine" and when he came to see me in November, 1915, informed me naively, quite unaware of its significance, that he had celebrated his birthday during the summer by—a moonlight motor boat party down the Great South Bay.

I trust that the presentation has given no offense. It is the result of a serious effort to unravel a serious medical complaint in what seems to me to be the most substantial way. Perhaps I may in justification again refer to *Pendennis* where Thackeray says in the preface, dedicated, by the way, in sincere gratitude to his own physician, Dr. John Elliotson, in part as follows: "Society will not tolerate the natural in our art. Many ladies have remonstrated and many subscribers left me, because I described a young man resisting and affected by temptation. You will not hear—it is best to know it—what is the life and talk of your sons. A little more frankness than is customary has been attempted in this story, with no bad desire on the writer's part, it is hoped, and with no ill consequence to any reader." The publication of this paper was deferred for over a year so that the permanence of the results might be determined.

249 West Seventy-fourth Street.

PERCUSSION IN EARLY TUBERCULOSIS.

By Julius Schneyer, M. D.
Philadelphia,
Clinical Assistant, Medical Clinic, Polyclinic Hospital.

Pulmonary tuberculosis is essentially a disease of intermittent course and of such complex symptomatology that its beginning is generally overlooked, passed over as a slight cold, or diagnosed as influenza, the acute condition subsiding without arousing suspicion. By the time the patient and his family apply to the physician for advice, the condition is fairly advanced and then it is not much trouble to make the diagnosis.

It is highly important, however, that the profession and the public should realize that a plain cold or so called grippe may be in fact the forerunner of a tuberculous infiltration in the lungs, and more time and skill should be devoted to investigation of these conditions and to an endeavor to make the diagnosis of tuberculosis in its incipiency.

Skill depends mainly on two factors: On the mental and manual equipment of the physician, and the amount of time he can devote to the acquirement of the technical dexterity and special knowledge needed to carry out the delicate manipulations and interpret the results.

The mere thumping of a chest wall and resting of an ear to its surface will no longer suffice. There is an enormous increase in the store of medical knowledge and wealth of technic, but there is no corresponding increase in the time, nor even the ambition of the rank and file of the medical profession, especially in this country, in order to keep pace with the increasing demands. This perhaps has tended toward the growing popularity of certain special laboratory tests which bear about them something of the glamour of science and the romance of novelty. This tendency has, in the writer's opinion, helped to retard rather than advance diagnosis, because it fostered neglect of the older methods of physical investigation, methods on which we must still rely, and which demand for successful applica-

tion the experience which only constant practice can give.

The newer methods of diagnosis, owing to their atmosphere of science and modernity, are often seriously misapplied. These modern laboratory, microscope and x ray methods of diagnosis are undoubtedly valuable, yet we cannot and we should not dispense with the old methods, and it is essential fully to master the subtleties of physical examination. If any skill is required in the investigation of the diseased condition of the chest, no opportunity should be lost in studying the normal in all its manifold and subtle manifestations and phases. It is essential to develop the so called medical instinct, which is based upon the intensification or high specialization of the senses of vision, olfaction, hearing, taste, and tactile sense, which are all indispensable factors for the practice of the art of physical examination, without which equipment the physician has no right to pursue his profession. I mean the art of inspection, palpation, percussion, and auscultation.

PERCUSSION.

The practice of percussion was introduced by Auenbrugger in 1760. He used direct percussion with his gloved finger tips. In 1826 mediate percussion appeared through the introduction of the pleximeter by Priorry. Since then the art has made no appreciable progress until recently.

The experimental investigations and researches of Roehl, Moritz, and subsequently of Goldscheider and others, succeeded at last in bringing before the attention of the medical profession the method of gentle percussion. In the detection of early tuberculous disease of the lungs its acknowledged value seems likely to produce far reaching results, for whereas formerly percussion took only a poor second place in the detection of early tuberculous infiltration, the newer method in skillful hands seems likely to compete with auscultation for a first place in diagnosis. There is no doubt that some change of resonance to gentle percussion accompanies very early lesions in the apex, indeed, it is the writer's experience that some alteration to skilled percussion can be found over every diagnosticable lesion, and that a diagnosis can rarely if ever be made without it.

This is not to deny the fact that the very earliest changes are auscultatory, but the slightest alteration of the breath sound cannot suffice for diagnosis, and other positive evidence is usually first obtainable by percussion. Moreover, in many cases a change of percussion note may precede auscultatory evidence of the disease, and if it occurs it is less open to other interpretation than are the changes in breath sounds, which represent the earliest signs.

An interesting research was carried out by Goldscheider with the help of Levy-Dorn into the comparative value of ordinary percussion, gentle percussion, and auscultation, with the evidence given by the x rays in cases of suspected phthisis. They found that gentle percussion discovered disease and confirmed by x ray diagnosis in many cases where ordinary percussion failed (thirty-eight cases), and that where ordinary percussion discovered changes at only one apex, gentle percussion was able to demonstrate disease confirmed by x rays at both (forty cases); thus demonstrating that cases are not missed by gentle percussion, which to ordinary percussion would have been overlooked. Finally, they found, that though auscultation gave better results than ordinary percussion, yet gentle percussion discovered disease in twenty-five per cent. more cases than did auscultation.

Kroenig says, "It is a very wide spread error to expect to find the earliest physical signs by auscultation." He points out that an auscultatory change depends on the lesion coming into direct relation with the air stream, and this may not occur. Furthermore, if it does occur, obstructed air entry over small areas is obscured by compensatory emphysema, and it is only when the disease has broken into the air tubes or involves so large an area as to cause weak breathing, that undoubted signs appear. Although accomplishment in auscultation must not be neglected, yet there is no doubt that gentle percussion is the easier of the two methods to learn and it gives more certain and fruitful results.

The best method of percussion to adopt for practical purposes is as follows: At first percussion should be very soft and gentle in order to elicit impairment of resonance, and then the force should be carefully and gradually increased in order to find out at what point impairment disappears.

If no impairment is found to fairly gentle percussion, softer and softer percussion must be tried, so as to bring out any possible shade of difference that exists between the two sides, and this must be continued until the note is only just audible. The most delicate change in the percussion note appears only at this point.

The comparison of the two apices is greatly facilitated in a difficult case by first marking out Kroenig's areas of resonance on the two sides. (See below.)

An equal percussion force can be assured only by percussing from the wrist with the weight of the hand. A single finger, the middle one, should be used, and it should be bent in hammerlike fashion. Over the apices gentle percussion alone can be practised and it has been abundantly proved that even the most deep seated parts of the lungs can be reached by soft percussion properly applied.

The plexímeter finger must be pressed close to the chest wall and percussed over the area of contact. The writer places the finger tip of the plexímeter finger obliquely, snugly on the chest wall and percusses over the area of contact. By this method we get information as to the pathological change of a small limited area, that can be covered by the finger tip. The method of placing the entire plexímeter finger flatly over the part to be percussed conveys the tones of a large volume of underlying tissue, and if the diseased area is small these tones will not be accurate enough to interpret all possible minute changes, as the resonant sounds of the surrounding healthy tissue obscure the abnormal note conveyed by the infiltrated area. For instance, if there is a very small area of consolidation, the surface of which is so small that it can be covered by the tip of the plexímeter finger, we get dullness or

impairment of resonance percussing by the method described, but percussing by the old method of placing the entire pleximeter finger on the chest we might obtain normal resonance which would obscure the diagnosis.

The percussing finger, as mentioned before, must be bent to a right angle, and descend vertically like the hammer of a piano, or the true resonance is not obtained. Sometimes the writer gets better results by percussing with the tip of the extended finger, descending not vertically but rather in a horizontal or slightly oblique fashion. Only similar points on the opposite side of the chest can be compared.

Comparing the percussion notes of the two sides we should have in mind what to listen for. More or less resonance is confusing, and it is best to fix attention on one of the many component parts of which the resonant note consists. This may be either fullness of note, quantity, quality, duration, or pitch, and of all these the easiest to appreciate is the pitch. We can readily differentiate a high pitched from a low pitched tone. If the finer shades of im-

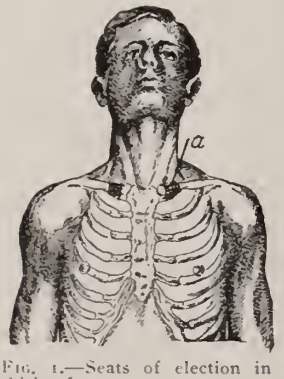

Fig. 1.—Seats of election in phthisis; front.

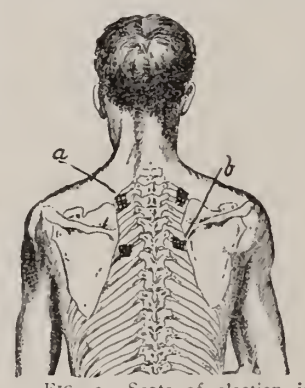

Fig. 2.—Seats of election in phthisis; back.

pairment are thought of as a rise in pitch of the note, or a production of a higher, sharper note (in the musical sense), the problem is greatly lightened and changes will be recognized, which would otherwise be missed.

The front of the chest.—The chest is best percussed with the patient standing. Breathing should be quiet, unrestrained; opposite points should be compared all down the chest and the difference on the two sides noted. In suspicious cases topographical percussion should be first resorted to. (See below.) The clavicles must not be neglected and these should be compared in finger breadths from within outward over their inner half. The seats of election for tuberculous deposits in front of the chest are in most cases behind the inner half of the clavicles (Fig. 1).

If impairment is discovered on one side of the chest, the clearer side must then be percussed from the base to the apex, for there may be impairment in the better apex also, although it has seemed resonant in comparison with the opposite one.

It may happen that the better note will be found to be on the diseased side due to an underlying emphysema. This is apt to occur with a healed or quiescent focus, and the relative impairment on the opposite side may lead to a false impression until other signs are discovered.

The back of the chest.—In examining the back the same proceeding is to be followed out as in front, and here especially each side should be repercussed from the base up. At the back of the chest there are two seats of election for tuberculous infiltration, and these are the apices of both the upper and the lower lobes (Fig. 2).

The upper apex reaches to the first dorsal vertebra and it is near the inner end of the supraspinous region where the signs of early tuberculosis are especially met.

The lower apex reaches up to the third vertebral spine on the right side and the fourth vertebral spine on the left side, and tuberculous deposit is commonly found below these points to about the level of the fifth thoracic vertebra and midway between the scapula and the vertebral column (Fig. 2). Some slight impairment of the percussion note may occur in one or both lower lobes at an early stage of tuberculosis and by their suggestive distribution they supply the most important evidence in deciding the significance of obscure signs at the apices. In percussing the back, we must remember that the note normally rises in pitch from below upward, but this occurs so gradually that we can hardly notice it. The rhomboid muscle runs from the spine of the scapula to its inferior angle, and the thick belly of the muscle is nearer the inner border of the scapula, which may occasion some impairment in the note. But near the spine the muscle is thin and it is not likely to cause an error.

Impairment of resonance in early phthisis. Some authorities may object to this method on the ground that the anatomical tubercle must attain considerable size in order to produce alteration in the resonant note. But such objection has no practical foundation, because as a matter of fact a very small lesion interferes with the lines of communication in the bronchi and vessels, causing considerable surface changes, mainly those of collapse. Birch-Hirschfeld has shown that the first tuberculous deposit occurs in the apical bronchi and causes collapse of the parts beyond. From the clinical point of view Oestreich was able to show, and prove by post mortem findings, that very early lesions produce a shrinkage in the apex.

The teachings of Birch-Hirschfeld are based on thorough investigations of 826 cases of accidental death. A number of the victims had lesions in the apex, and in most of them the tuberculous infiltration occluded the lumen of a bronchus, always the posterior branch and caused collapse of the apex or the wedge of the lung peripheral to it. In practice it is shown that impairment, though slight in degree, is by no means narrow in extent, and it is not easy to explain the reason for this phenomenon. Many factors may enter into its causation; probably a thickened pleura, or changes in the air and blood contents of the surface layer.

Kroenig believes that pleurisy occurs early in pulmonary tuberculosis. There is also a possibility that there is some spasm or rigidity of the muscles of the affected side, causing some impairment of resonance.

Expiratory percussion. Over the normal lung

the percussion note is more resonant in expiration than in inspiration on ordinary percussion. In disease the normal change is disturbed, and this fact may be utilized in diagnosis. In tuberculous lesions the impairment of the percussion note is even more accentuated in expiration than in ordinary breathing. Thus expiration may be used in order to enable the examiner to appreciate the difference between the sound side and the diseased one because expiration increases resonance in health and diminishes it in disease.

The patient is directed to let the air out of his lungs and hold his breath while percussion is performed and the note compared on the two sides. Some observers, who fail to recognize any change to ordinary percussion, may readily appreciate it when it is reinforced by this simple method.

Topographical percussion. Careful mapping out of the apex of the lung is a method which will repay time and trouble and should never be neglected in any case where a diagnosis of incipient pulmonary tuberculosis is doubtful. Kroenig, using light percussion, introduced an excellent method by which he mapped out the boundaries of resonance above the clavicle. He attempted to prove this method to be in conformity with the anatomy of the apex, which was found to lie further from the vertebral column than it was previously supposed to be. After much labor on his inner boundary, he was led to map out an outer boundary of the resonant space above the clavicle and he carried these boundaries over the shoulders anteriorly and posteriorly, thus forming an anterior and posterior area of apical resonance united by a narrower "isthmus" (Figs. 5 and 6.) Their determination and comparison form a method which is known under the name of Kroenig's method of topographical percussion.

A diagram of the lungs in their relation to the chest clearly shows the apex in front to lie behind the heads of the sternomastoid muscle above the inner end of the clavicle (Fig. 3), and this can be seen by watching its protrusion at this point in thin subjects during cough, or in wasted infants during crying. Behind, the apex is found to reach the first dorsal vertebra between the spinous process and the origin of the first rib (Fig. 4). The true apex as shown bears no direct relationship to Kroenig's area of resonance. This was pointed out by Goldscheider, in 1907, and he recommended mapping out the apex in front by percussing between the heads of the sternomastoid muscle and behind at the first dorsal vertebra between its spinous process and the origin of the first rib. We have therefore two methods at our disposal: Kroenig's method and Goldscheider's method. Goldscheider teaches how to outline the true apex in front and in the back, and Kroenig's method is concerned with the measurement of a resonant area formed by the projection of the outer surface of the apex in various directions.

As a matter of clinical experience Kroenig's sign is of considerable utility in the diagnosis of early tuberculosis and of other apical lesions. Oestreich was able by its means to detect foci the size of a cherry, in experiments on post mortem material, and he finds a shrinkage of the apex in very early stages of pulmonary tuberculosis. Other clinical authorities have mostly endorsed this opinion. The application of Goldscheider's method in actual practice is much more difficult. The resonance of the apex between the heads of the sternomastoid muscle is very hard to map out, as the apex reaches a little more than a finger breadth above the clavicle. Behind, the true apex of the lung is separated from the surface by a rib and transverse process (Fig. 4), and by a thick pad of muscle lying between these and the vertebral spine, Goldscheider's percussion, as carried out by himself, is an extremely difficult and laborious undertaking.

In addition to marking out the upper limit, he sets out in front to percuss over the first rib above the clavicle, the shoulders for this purpose being raised and loosened, so that the pleximeter finger can dip down to the first rib beneath. Behind he removes the scapula as far as possible from the field of research by seating the patient with the arms thrown forward over a vacant chair. Taking the evidences discussed into consideration, and as a result of practical experience with both methods, the writer would recommend reliance on the following points:

To use Goldscheider's method, the upper boundary of the apex behind is marked out on each side, percussing gently from below upward and the height of the apices on the two sides is compared (Fig. 9). Normally the lungs should reach to the tip of the spinous process of the first dorsal vertebra, and the investigation of this point is easy and furnishes useful information. In front the resonance on the two sides between the heads of the sternomastoid muscle should be compared, but no attempt at measurement should be made.

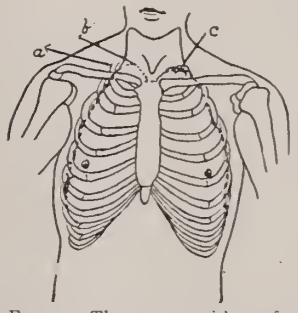

FIG. 3.—The true position of the lung apex in front.

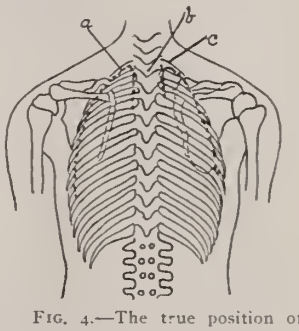

FIG. 4.—The true position of the lung apex behind.

Kroenig's method is better seen than described, and the reader is referred for this purpose to the accompanying diagrams (Figs. 5 and 6). In order to outline Kroenig's resonant fields, the writer proceeds as follows: The pleximeter finger of the left hand is placed in such a way that the terminal phalanx only touches the middle of the shoulder, and with the tip of the middle finger of the right hand a few very gentle strokes are given at the place of contact, and a sound which is not loud but distinctly audible, clear, and resonant is heard. These strokes are repeated and attentively listened to, and the same clear resonant sound is heard. This is done in order to become familiar with this note. This resonant tone is due to the underlying pulmonary tissue, which is filled with air. The pleximeter finger is moved slightly inward and a few more light strokes are given. The same sound

is heard; there is still lung tissue. Gentle percussion is continued in this manner, gradually moving the plexímeter finger until a place is reached where the familiar resonant note is no more heard, but instead, an almost inaudible, dull, and higher pitched sound, which means that there is no more lung tissue to convey the same acoustic vibrations. At the very edge of the resonant area a pencil mark should be made. Gentle percussion is continued outward toward the acromion process of the scapula in the

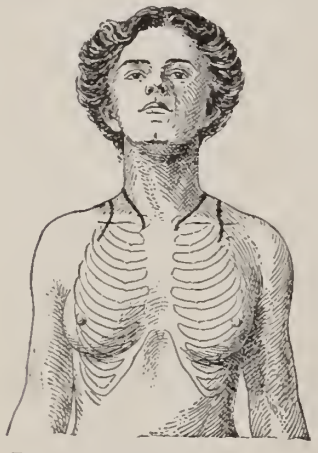

Fig. 5.—Kroenig's areas of apical resonance; front.

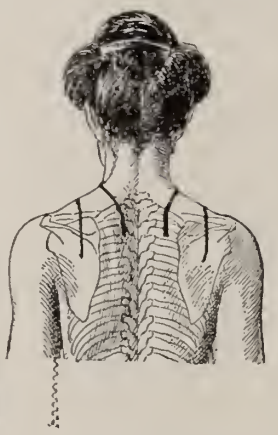

Fig. 6.—Same as Fig 5; back.

same manner until another place is reached where the resonant sound ceases to be heard, and this place is also marked with a skin pencil. In a similar manner the entire area above the clavicle anteriorly, and as far as the level of the first thoracic vertebra posteriorly, is percussed, the edges being marked with the pencil and carefully verified after they are marked. It must be remembered that the plexímeter finger has an appreciable width, and the whole breadth of the finger must cover resonance before the edge is penciled. The head must be directed straight forward throughout the examination.

It must also be noted whether the edge is sharp and easy to map out, since blurring of the outline, especially on the inner side, is one of the earliest signs of disease (Fig. 7). Where the edge is not sharply defined, an attempt must be made to map out a band of relative resonance within (Fig. 8).

When each side is mapped out, the "isthmus" should be measured, and, if desired, the bases at the clavicle in front and at the level of the first dorsal spine behind. The isthmus in health measures generally about five cm. (two inches) and should not fall below four cm. A diminution in Kroenig's area is an early sign of tuberculosis. Having taken these measurements, the percussion resonance of the two sides should be compared, which is done by finger breadths above the clavicle.

AUSCULTATORY PERCUSSION.

Another excellent method of outlining Kroenig's areas, which verifies the findings of the foregoing method with almost mathematical precision and exactness, as practised by the author, is that of auscultatory percussion.

The stethoscope is placed either in front of the chest immediately below the clavicle, or posteriorly between the upper angle of the scapula and the vertebral column (Figs. 7 and 8). A light tap or stroke is given over the middle of the shoulder. A loud and clear note is audible. This is due to the acoustic vibrations conveyed to the stethoscope by the underlying lung tissue. Then another stroke or tap is given a little higher up, and another loud sound is heard, which shows that there is still lung tissue. And in this manner stroking or tapping is continued until a place is reached where the loud sound is no longer heard, but a distant, low, hardly audible note. This is the inner boundary of the apex, which should correspond with the same found by gentle percussion. In the same manner the outer boundary is discovered, and should also coincide with that found on gentle percussion. This method has the advantage over gentle percussion that it may be practised even in a noisy place, because the binaural stethoscope eliminates all external sounds. It also enables the examiner to verify the correctness of the results found on gentle percussion with almost mathematical exactness.

The earliest changes in cases of tuberculous infiltration consists in a blurring of the outline of Kroenig's area (Fig. 7). This may occur on both outer and inner sides, but it commonly affects the latter at first. This is attributed by Kroenig himself to a change of tension in the lung tissue at the margin of the affected area. He accepts the explanation of Birch-Hirschfeld that the earliest change is in the apical bronchus, the obstruction of its lumen with tuberculous material leading to stasis and absorption of the air in the parts beyond. This blurring of its outline leads to difficulty in marking out the area of resonance, and soon a definite reduction of its surface appears and impairment over it. These changes may precede auscultatory signs, also

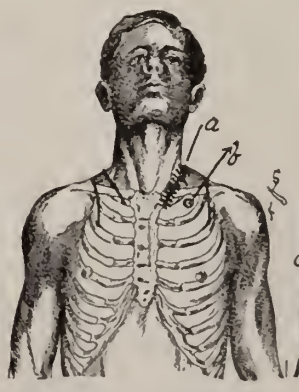

Fig. 7.—Kroenig's area; showing retraction at the right apex and blurring of the inner boundary of the left apex.

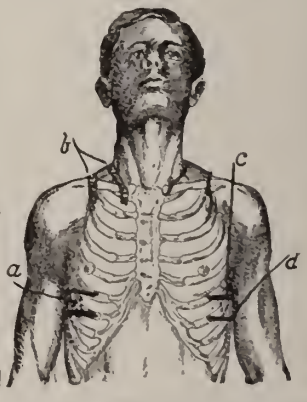

Fig. 8.—Kroenig's area showing boundaries of relative resonance at the right apex.

symptoms such as cough and expectoration. The physical examination of a difficult and doubtful case of phthisis is not complete without the comparison of Kroenig's areas of resonance.

Tidal percussion. Tidal percussion discovers the excursion of the lung in the complemental pleural space during inspiration and expiration.

At the apex the movement is best measured by marking the highest point of the apex, that is the inner boundary of Kroenig's area (Fig. 5) during

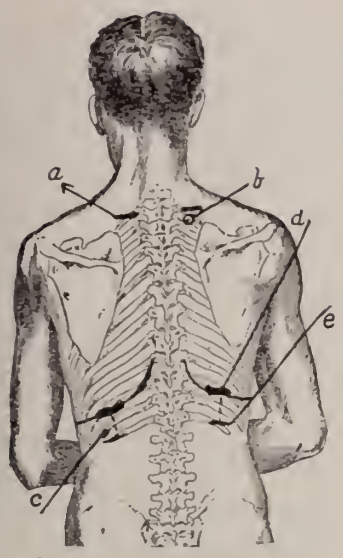

FIG. 9.—Tidal percussion; back.

quiet breathing and again during deep inspiration, and then comparing the expansion of the apex with that on the opposite side. This may be accomplished either by gentle percussion or by auscultatory percussion, or by both methods, one confirming the other.

At the base of the lung, expansion is notably greater and furnishes valuable information. The excursion of the lung is indicated in Figs. 8 and 9. The writer finds that the most convenient points at which to take the measurement are the anterior axillary line and the centre of the base behind (Figs. 8 and 9). The edge of the lung is percussed during quiet breathing and marked with an anilin pencil on both sides. The patient is directed to take a deep inspiration and hold it, and the edge is again found by percussion and marked.

Normally the lung descends quickly and clearly into the pleural space, and a vertical measure, varying with the individual and the vigor of respiration from three and a half to six and a half cm., is obtained. The excursion is generally more in the anterior axillary line than posteriorly, and is apt, in the writer's experience, to be somewhat more on the left than on the right side in health. Moreover, it will be noticed that the base of the left lung lies some cm. lower than that of the right lung during quiet respiration. Allowance in amount of excursion must be made for emphysema, where the movement is minimal but equal on both sides, for advancing age, and for such conditions as chest deformity, pain in the side, ignorance of how to breathe, and other conditions which prevent full expansion on one or both sides. In tuberculosis the excursion of the lung is generally diminished on the affected side, even in early stages. Where disease is well marked the inspiratory movement may be greatly restricted or absent. How far this condition is due to pleural adhesion is doubtful; it is certain, however, that pleurisy occurs at an early stage of tuberculosis, and the influence of adhesion is rendered probable by the fact that limitation of movement is frequently confined to one aspect of the lung, either anterior or posterior. This sign is of value in the diagnosis of phthisis, always remembering that it may be absent or inappreciable and that pleural adhesion may be present without active disease.

As a measure of the extent of pleurisy in any case of phthisis, in order to decide as to the advisability of artificial pneumothorax, the measurement of the degree of the movement or expansion of the lung is of notable value.

CONCLUSIONS.

Impairment of one apex points to an abnormality needing investigation. It may indicate that there is a tuberculous deposit, or local pleurisy in one apex of similar causation, or an apical collapse due to a peribronchial tuberculous infiltration. In order to decide as to the cause and nature of the lesion, which has produced impairment of the percussion note, further investigation must be made. Percussion alone is capable of solving the following questions:

1. Is there impairment of resonance in one apex? This can be discovered by the softest percussion, having in mind the possibility of hyperresonance on the opposite side. Reinforcement by expiratory percussion may be tried in doubtful cases. These cases are often overlooked or missed if ordinary percussion is used.

2. As to the degree of impairment, we may determine it by increasing the weight or force of percussion in order to see if it still persists or at what point it stops.

3. The most important evidence for diagnosis is the finding whether there is any impairment at the other "seats of election" for tuberculous deposits, for instance, in the opposite side or at the apices of the lower lobes.

4. Topographical percussion may supply us with the following information: *a*, Equal resonant areas and of normal extent are evidences of normal lungs (Figs. 5 and 6). The areas of normal measurement, but one being displaced, is a condition described by Kroenig under the name of "physiological heterotopia." It was this condition which led Kroenig to discover his outer boundary. *b*. There may be a blurring of one, or the other, or both margins of the resonant area with or without some general loss of resonance, a condition very suggestive of early tuberculosis. *c*. A difference of the areas and especially in the width of the "isthmus" may be due either to expansion of one side, or retraction of the other (Fig. 7), or both conditions may be present.

Expansion may be due to unilateral emphysema, which is commonly caused by a "healed in" tuberculous focus with scarring. Retraction may be due either to some recent or remote tuberculous change, or to collapse, or to induration as a result of collapse.

5. Auscultatory percussion as practised by the writer, is of notable value for confirmation of the findings by gentle percussion in outlining Kroenig's areas, or mapping out the respiratory excursion of the lung borders, especially when external noise prevents appreciation of the delicate shades of difference in sounds by gentle percussion.

6. The diminution in the respiratory excursion of the lower border of one lung is an early sign of tuberculosis. We must exclude emphysema, old age, pleurisy, pain, inability to breathe, or other conditions interfering with the free movement of the lung in the pleural space without active disease.

7. Fully appreciating the value of all the modern diagnostic methods, I wish to say that the old methods are of primary importance. A capable physician is not he who is able to analyze urine or sputum, or use the microscope, etc., but he who is skill-

ful with the old methods of inspection, palpation, percussion, auscultation, and mainly the taking of a good history. One who relies solely and principally on laboratory methods for diagnosis is making a big mistake. In order to acquire the necessary skill the medical man must have the eye of an eagle to notice and observe all possible changes occurring in health and in disease, he must be able to penetrate into the very depth of human nature; he must have a well trained ear in order to hear, appreciate, and interpret all possible differences of sound, which is most important in auscultation and percussion. He must develop his tactile, olfactory, and gustatory senses, all for the purpose of diagnosis. He must talk medicine and think medicine. In a word he must have the faculty which we call medical instinct, which enables the physician so often to recognize disease at a glance. And above everything the doctor must have a good reasoning power, the gift of observation, quick perception, common sense, and a logical mind in order to interpret the different phenomena and make correct deductions. And only then when he acquires all these essential attributes, he may frequently resort in doubtful cases to the newer, more scientific laboratory tests as excellent aids to diagnosis.

SALIVARY SUPERSTITIONS.

By Howard D. King, M. D.,
New Orleans, La.

The habit of promiscuous expectoration is an uncleanly and disgusting one, but how curious it is that it should be environed with so much superstition. In days of antiquity spitting was resorted to in order to ward off danger, and up to the present time luck is wooed and misfortune avoided by the process of spitting. Newborn children are treated to a lavish expectoration by a certain class of midwives; fishermen spit upon their hooks after baiting them. It is considered by some to be absolutely essential before washing in water in which a friend has washed to spit into it, otherwise a quarrel is sure to follow.

But it is in old Europe that the superstition of spitting seems to reach its worst degree. In Oldenburg, for example, the loathsome custom prevails of always spitting three times into the kneading trough before the dough reaches the oven. Again, babies in Hungary are especially singled out as the objects of the superstition; the custom there is to spit into the baby's face in order to bring it good luck. Imagination almost fails to picture the filthiness and danger of such a disgusting act. In Silesia and Bohemia, persons generally spit three times when they meet an old woman, but it is quite difficult to conceive why the presence of an aged female should call for such a profligate evacuation of the salivary secretion. In Sweden a great deal of superstitious spitting also takes place. Persons spit into their beds before retiring; playing cards are spat upon when luck is bad, and every new suit of clothes is made the object of a salivary demonstration.

The widespread belief in the wonderful powers possessed by saliva is, however, not always allied to imaginative superstition, but often seems to savor of empiricism. In parts of Scotland warts on the hand are supposed to vanish with great celerity should they be anointed each morning with the first spittle formed by their owner's salivary glands after awaking. The most extraordinary part of the story is that there seems to be a degree of truth in it. In America the curative power of spittle is vouched for by many of the intelligent classes. The wounds of dogs are said to heal best if treated solely with the injured animal's tongue.

The Gaelic race has ever been deeply absorbed in legendary fancies and mythical creations, many of which are connected with spitting. Ireland is noted for its many evil minded people. In many cases the evil minded person is compelled by the injured man, on pain of bodily damage, to spit upon the object of his pretended admiration, and at the same time to invoke a blessing on it. Admiration from an evil minded person is always regarded as of ill omen. In Connemara a bowl is sometimes sent around the neighborhood, and each person to whom it is presented is expected to spit into it. The bowl is then taken home, and the person or animal overlooked is anointed with spittle. The object of this is to obtain the spittle of the person responsible for the injury without giving him offense or awakening his suspicion, as a direct appeal to him would be certain to do.

In many parts of Ireland thrush in children is cured by having a posthumous child blow into the mouth of the sufferer. The blowing must be done by the operator while fasting, and is generally repeated on three successive mornings. In county Meath the cure of warts is accomplished by first spitting upon the hearth immediately after arising; following this a second installment of saliva is hawked up and applied to the wart. In applying the spittle to the wart the second finger must be used. The use of the first finger would be disastrous. In county Mayo styes are treated by liberal applications of spittle.

In certain parts of Ireland, principally the west, the name Mearnan and spittle are indissolubly linked. A woman by the name of Mearnan with an evil eye made admiring remarks on the limbs of her neighbors. These words of admiration caused all of them to become cripples. One young man whose feet she deformed by her complimentary remarks, compelled her to bless his feet and spit upon them. His limbs were soon restored to their normal condition. One of the Mearnans was so well aware of the blighting influence of his evil eye that upon entering a home to pay a visit he would always spit upon and bless each member of the family before sitting down.

Superstitions are said to die hard; and it would seem from the foregoing facts that the one under

discussion has been endowed with a phenomenal vitality. Despite its absurdity, filthiness, and unhygienic character, the salivary superstition has still survived; whereas, on sanitary grounds, it should, without further loss of time, be buried and never be revived.

Medical Building.

SYPHILIS OF THE LARYNX.

With Gumma of the Left Vocal Cord,

By Joseph Weinstein, M. D.,
New York.

The following case is submitted primarily to call attention to a long delay in giving efficacious treatment to a patient, a delay which might have been avoided had a Wassermann been done at the beginning as a routine procedure.

Syphilis of the larynx is a condition infrequently met. Reports vary as to its frequency from 0.4 to thirty per cent. Alfred Bruck, who has made it a practice to examine the throat of every syphilitic patient, places it at 1.5 per cent. It is seen in the secondary or tertiary stage after a lapse of from several months to twenty years after the primary infection. Primary infection in the larynx is most rare; Krashaber reported a case in 1877, and Moure a case in 1890.

Early symptoms of laryngeal syphilis are usually of so mild a character as to go unrecognized by both the physician and patient. The patient frequently has no recollection of the primary or secondary stage or of any infection, hence the value of a Wassermann in all throat infections. In the secondary stage the lesions are usually erythematous or condylomatous in character. Catarrh, hoarseness, and mucous patches should always arouse suspicion. Tertiary lesions are gumma, ulceration, and scar tissue. The gumma is seldom seen. It is dark red in color, protruding, and hard.

Paralysis of the vocal cords is frequently present in laryngeal syphilis and is probably due to an infiltration of the muscles; or it may be due to pressure on the recurrent laryngeal nerve.

Tertiary syphilis may easily be mistaken for tuberculosis or even carcinoma. A diagnosis is rendered particularly difficult if both syphilis and tuberculosis are present. Syphilitic symptoms are usually more acute, the infiltrations breaking down more rapidly. A diagnosis of carcinoma can best be made histologically. Treatment given for syphilis will often clear up the diagnosis, but does not always do so. Syphilis and carcinoma may also be present at the same time.

In syphilis of the larynx, the prognosis is favorable when the patient is seen at an early stage; the results are often brilliant. Where considerable progress has been made by the disease and where scar tissue has already formed, the chances of marked improvement are small. The condition is a grave one, complete and permanent paralysis of the vocal cords, destruction of the cords and of adjacent structures, and serious difficulty in swallowing being some of the complications. In the tertiary stage grave symptoms of stenosis may occur, rendering immediate tracheotomy necessary. In the case below had the condition been allowed to go on, permanent destruction of the larynx would have ensued.

Case. P. R., thirty-seven years old, first seen December 5, 1914. December, 1913, patient noticed slight hoarseness, which entirely cleared up in a few weeks. August, 1914, hoarseness reappeared; gave it no attention, as no other symptom accompanied it. After two weeks noticed that it was becoming daily more difficult to talk. Received medical attention for two weeks with no result. At end of third week, it was practically impossible to talk. Consulted a specialist, who advised no attempt to talk. Was treated for six weeks with no result. Continued the treatment for six weeks longer, however, still with no result, when he consulted another specialist, who pronounced the condition incurable.

December 5th, in my first examination, I found the posterior wall, epiglottis, and all other structures, including the right vocal cord, normal. The left vocal cord was reddened and infiltrated. Was movable. The question as to whether this was a cyst of the cord or a gummatous infiltration was decided when a Wassermann showed a four plus reaction. No history could be obtained of any venereal infection. The patient remembered, however, having had some trouble with his left hand about eight years previously, little sores appearing from time to time, but healing readily under local treatment.

No time was lost in administering antisyphilitic treatment after the Wassermann report. A full dose of neosalvarsan was given at 8.30 p. m. The patient retired at 9.30 and awakened at 1.30 a. m., at which time he noticed that his throat felt free and he spoke at once in his habitual voice and was able to do so without difficulty subsequently. A later examination showed a perfectly normal larynx with slight congestion of the left cord.

The dire results, probable and possible, had a correct diagnosis not been arrived at in the foregoing case compared with the brilliant result obtained *after* such a diagnosis, seem to speak in words sufficiently powerful to show the physician his duty to every patient in carefully considering syphilis in his differential diagnosis.

INTERPERITONEAL ADHESIONS

And Their Prevention,

By R. J. Behan, M. D.,
Pittsburgh,
Surgeon, St. Joseph's Hospital,
And W. A. Nealon, M. D.,
Pittsburgh.

Owing to the indefiniteness which exists at the present time in regard to both the cause and the manner of the formation of adhesions in the abdominal cavity, it seemed that a study, with the idea of determining the cause of the intraabdominal formation of adhesions and the manner of their prevention, would be of value. In the routine of the study it was thought necessary to define:

A. If alcohol in the peritoneal cavity can cause adhesive formations.

B. If glycerin in the peritoneal cavity can cause adhesive formations.

C. If denudation of only one or two opposing surfaces will give rise to adhesions.

D. If infection (mild or severe) is necessary for adhesive formation.

E. How peritoneal infection or inflammation produces adhesions.

F. Can toxins or bacteria passing out from the intestine give rise to adhesions?

In studying the prevention of adhesive formation in the abdomen it became necessary to—

A. Determine if petrolatum applied over raw areas will retard adhesive formation.

B. Determine whether wool fat, an organic fat alone, or mixed with some inert or soluble substance, as boric acid, inhibits adhesive formation.

C. Will olive oil in the abdominal cavity retard adhesive formation?

D. Will Russian oil prevent or hinder adhesive formation?

We elected first to study determination B, and later on incidentally to define the causes of adhesive interperitoneal formation.

Of the many methods of preventing the formation of adhesions—such as the injection of mineral and vegetable oils, and even of animal fats, or of solutions of the various metallic and nonmetallic salts, into the peritoneal cavity—none have proved entirely satisfactory. However, in reviewing the methods intended as preventive, it occurred to me that sufficient consideration had not been given to the cause and manner of the production of adhesions.

It seemed that adhesions between coils of intestine must have a cause other than mere abrasion of the serosa. In many cases it was observed during a secondary operation that the peritoneum was in excellent shape as far as adhesions were concerned, when we were sure that considerable traumatism had taken place during the primary operation. Apparently something more than traumatism was necessary for the production of adhesions between two adjacent peritoneal surfaces. This additional factor may be infection of a mild type, possibly due to some bacterium or toxin which has penetrated the intestinal wall.

The previous methods of preventing adhesion formation apparently did not take sufficiently into consideration either the possibility or the presence of this infection: and also discounted that other most important factor, namely that in using olive oil or a mineral oil, such as petroleum or refined oils or petrolatum, a foreign substance was being introduced into the peritoneal cavity. The natural reaction of the peritoneum to this foreign material would be the throwing out of exudate with fibrin deposit and subsequent adhesive formations.

In the hope of deriving some information along these lines we performed a few experiments to determine whether a paste of boric acid (five per cent.) in wool fat will inhibit peritoneal adhesions. The wool fat was chosen because it is an animal fat and would be best tolerated by the sensitive peritoneum. The boric acid was used as antiseptic in order to counteract any mild infection which should occur on the abraded peritoneal surface.

Experiment I. The first experiment was on March 23, 1915. The abdomen of a dog was opened and an enteroenterostomy performed. The omentum was stitched into the lower angle of the anastomotic area because of the difficulty of serosera approximation. At this place there was considerable bleeding. Bleeding was also present in the area of the abdominal wall where adhesions had been separated. In both these areas a sterile preparation of five per cent. boric acid in wool fat was rubbed in. This seemed to control the bleeding to a considerable degree (for this reason it might be used as a hemostatic). The incision was closed.

Experiment II. The abdomen was opened May 14, 1915. Adhesions were entirely absent around the area of anastomosis. The omentum was adherent, but was glistening. No adhesions to the peritoneum at incision margins were found. This compares favorably with the number of adhesions found after the first operation performed on February 28, 1915, for when, on March 23rd, the abdomen was opened, adhesions were everywhere present. The last operation was more careless—there was more free blood in the abdomen at the conclusion of the operation than at the conclusion of the first operation; also, care was not especially exercised to stop the bleeding. The result in this instance may apparently be ascribed to the local application of wool fat and boric acid. The abdomen was closed without the application of boric acid and wool fat.

Experiment III. The abdomen was opened September 20, 1915. Adhesions were marked—especially the omentum to the line of incision. Also stray bands of omentum were adherent to the small intestine. Two opposing surfaces of the small intestine were denuded of peritoneum. On one of the surfaces two silk sutures were inserted as guides. Wool fat and boric acid (five per cent.) was applied to each of the opposing surfaces. The abdomen was closed.

Experiment IV. The abdomen was opened October 22, 1915, with the assistance of Doctor Nealon; the omentum was found tightly adherent to the peritoneum in a wide area immediately beneath the site of the last incision. These adhesions were so dense that they could not be separated. The place on the bowel where the serosa had been scraped off at the previous operation was found. The two sutures were not identified, but the bowel itself was easily identified by the dark color of the serosa at this point. The bowel at this place seemed to be covered by new membrane which was easily rolled between the fingers. On the free margin of the bowel a projecting apron of peritoneum was seen. No other adhesions were observed.

As a means of defining a few of the conditions necessary for adhesion formation, two bowel segments were brought together.

At A, both adjacent peritoneal surfaces were scraped clean.

At B, one peritoneal surface was scraped.

At C, neither peritoneal surface was scraped.

Very slight aseptic precautions were taken; the instruments were sterilized, the towels were not, and the dog's skin was not too clean. The dog was rather restless for a few days, but quickly recovered and then was as active as ever.

Experiment V. On December 8, 1915, Doctor Nealon assisting, the abdomen was opened. The omentum was attached to the parietal peritoneum in a wide area and was very firmly joined. The intestine was matted together by adhesions partly derived from adjacent coils of intestine.

The area of intestine previously prepared was sought, and it was noted that in the upper angle where the two adjacent serosæ had been scraped union was firm; at B, where only one surface was scraped, union did not occur, but a free portion of a pseudoomentum which had been hanging down from the bowel was attached by a thin filamentous band; at C, neither side was attached; the serosa was free.

The experimental area was excised. The intestinal anastomosis which had been performed on March 22, 1915, was found. Adhesions were absent and the serosa was absolutely smooth. This was the area over which wool fat-boric paste had been smeared. Thus even in the presence of profuse adhesive formation in the peritoneal cavity, the application of wool fat and boric acid showed permanence of results.

Encouraged by the results of these experiments, I determined to use the wool fat-boric acid paste in the human abdomen. So far I have used it in fifteen operative cases with good results. Up to the present none of these patients have complained of symptoms which could be traced to adhesions.

though it is not long enough since the first case to determine whether the danger or the tendency to adhesive formation has been entirely obliterated. In all these cases there has been a post operative elevation of temperature beginning within the first twenty-four hours and dropping to normal within a few days. The pulse, as a rule, does not increase in rapidity. The patient complains of but little postoperative pain. Because of the apparent ease it brings to the patient, its seemingly entire harmlessness, and its evident power to inhibit adhesive formation, it has become my routine to use it in all cases where there is a possibility of postoperative adhesive formation. A detailed study of case histories will be published in the near future.

LABORATORY AIDS IN THE DIAGNOSIS OF POLIOMYELITIS.

By JOSEPHINE B. NEAL, A. B., M. D.,
New York,
Chief, Meningitis Division, Bureau of Laboratories, Department of Health, City of New York.

It is well known that sporadic cases of poliomyelitis are frequently seen when no epidemic exists. Because of this fact, during the past six years, it has been the lot of the meningitis division of the department of health to study, both clinically and by means of laboratory methods, many cases of this disease before the present epidemic occurred. Most of the cases seen by us, both before and during this epidemic, have been atypical and we have, therefore, been compelled to consider our laboratory findings with more than ordinary care. As with most such procedures, the answers which the laboratory returns to our questionings, furnish us with evidence that is corroborative only and by no means absolutely diagnostic.

Perhaps one of the most interesting experiments employed in the study of poliomyelitis has been the inoculation of monkeys by means of washings from the respiratory and alimentary mucous membrane. This was first successfully performed by Kling, Pettersson, and Wernstedt, in 1911. It has since been repeated several times. Doctor DuBois, Doctor Zingher, and I obtained washings from the nose and throat from an abortive case two weeks after the incidence of the sickness. With these we produced typical poliomyelitis in monkeys. In sections of the brain, from one of these monkeys, a few globoid bodies similar to those described by Flexner and Noguchi were found. A report appeared in the *Journal A. M. A.* for January 3, 1914.

Another laboratory method of some diagnostic value is the so called neutralization test. In this, serum from the suspected case in the stage of recovery is mixed with a known fatal dose of an active virus. These are incubated and later injected intracerebrally into the monkeys. Failure of the disease to develop indicates that the virus has been neutralized. This test, however, does not furnish conclusive evidence of poliomyelitis, for serums from those known to have been free from a recent attack of the disease have sometimes successfully neutralized the virus. It is, however, quite obvious that laboratory methods requiring the use of monkeys are both too complicated and too costly for ordinary diagnostic use.

A study of the blood picture was exhaustively made by Peabody, Draper, and Dochez, of the Rockefeller Institute. It was shown that there existed a varying increase in leucocytes and a polymorphonucleosis. This is characteristic of so many other diseases that it is of little help in diagnosis.

The procedure which we find to be our most trustworthy and valuable aid in the recognition of poliomyelitis is the examination of the spinal fluid. In the first twenty-four to forty-eight hours after its onset, poliomyelitis must be differentiated from the early stages of epidemic meningitis, or mild purulent meningitis, and also from a meningism accompanying pneumonia or other infection. The clinical pictures presented by these diseases are quite similar, and it is in distinguishing between them that the examination of spinal fluid affords us the most valuable information. In the early stages of poliomyelitis, the spinal fluid is clear, or rarely, it may be slightly cloudy. It often shows a good fibrin web formation. There is a slight to moderate increase of albumin and globulin and also of the cellular elements. The reduction of Fehling's is prompt. Those poliomyelitic fluids which are cloudy present a polymorphonucleosis which may run as high as ninety per cent., but which we usually find to be about sixty per cent. As a rule, however, eighty per cent. or more of the cells are mononuclears. In examining such fluids we have frequently observed the presence of large mononuclear cells which we believe to be in a measure characteristic of poliomyelitis. We are now studying these by means of the various differential stains in the hope that our research in this direction may bring out something of positive diagnostic significance.

Two rare types of spinal fluids sometimes occur in poliomyelitis when the hemorrhagic process has been more than usually extensive. The first of these is of the true hemorrhagic character, the red blood cells being evenly diffused throughout the fluid. When collected in successive tubes, the specimens are all homogeneous, showing no change in the intensity of the hemorrhage. This serves to differentiate it from bloody fluids obtained by the accidental puncture of a vein. The second of these rarer fluids illustrate the so called syndrome of Froin. It has a characteristic yellow color and coagulates spontaneously. As these fluids are found in other conditions they are not pathognomonic of poliomyelitis.

The spinal fluid from early cases of purulent meningitis shows a varying degree of cloudiness, except in very rare instances when it may be clear. A greater increase in albumin and globulin is usually found here than occurs in poliomyelitis with a poorer reduction of Fehling's. The cells in these fluids of purulent meningitis are ninety per cent. or more polymorphonuclears, and the etiological organism is found except in the mildest cases. In certain mild cases of meningitis probably of epidemic variety the meningococci may never be positively demonstrated in the fluid. In purulent meningitis due to other organisms, these practically al-

ways appear later as the necessity for further lumbar puncture develops. In one instance, I have seen a clear fluid from an early case of epidemic meningitis. This was of about eighteen hours' standing. Although the cellular reaction was so slight, the meningococcus was demonstrated to be present in the fluid by smear and culture. The fluid in meningism is differentiated by being increased in amount, but it is practically normal in character.

When seen a week or more after the onset, cases of poliomyelitis, especially if they present cerebral symptoms, must be differentiated from tuberculous meningitis. The spinal fluid in both these conditions is clear and increased in amount. The albumin and globulin content of both is also increased, but usually in poliomyelitis, the increase of both elements is not so great as occurs in tuberculous meningitis. The reduction of Fehling's is usually better and, here let me say, that many tuberculous fluids give a good reduction of Fehling's, though the contrary has been stated. The cellular element is also usually less in poliomyelitis. In both conditions at this stage there is ordinarily a mononucleosis, although in some acute cases of tuberculous meningitis there is a polymorphonucleosis. If, however, as *may* happen occasionally, the increase of albumin and globulin is greater than usual, and the reduction of Fehling's is not so prompt, then the determination of the disease must wait upon the results of animal inoculation if it has been impossible to demonstrate tubercle bacilli in fluids.

A detailed study of the fluids of poliomyelitis examined by the meningitis division was made by Dr. H. L. Abramson, of that division, and published in the *American Journal of Diseases of Children*, November, 1915.

In brief, then, a spinal fluid increased in amount and showing a slight to moderate increase in albumin and globulin, a good reduction of Fehling's, and a varying cellular increase mostly mononuclear, makes the diagnosis reasonably certain in fairly early cases of suspected poliomyelitis. A slightly cloudy fluid occurring very early in the disease must be differentiated, as noted above, from a similar fluid in an early purulent meningitis. Fluids from the cerebral or encephalitic type of poliomyelitis may sometimes be differentiated from fluids of tuberculous meningitis only by animal inoculation.

Abstracts and Reviews.

THE NATURE, MANNER OF CONVEYANCE, AND MEANS OF PREVENTION OF INFANTILE PARALYSIS.

BY SIMON FLEXNER, M. D.,
Rockefeller Institute, New York

Doctor Flexner made his remarks in language easily understood by the laymen present in the large professional audience. He explained that as the Rockefeller Institute for Medical Research had been appealed to by many physicians and laymen for information and advice on the subject of infantile paralysis, it seemed desirable to relate the facts of present knowledge concerning certain highly pertinent aspects of the disease, together with deductions of practical importance.

Infantile paralysis was an infectious and communicable disease, caused by the invasion of the spinal cord and brain by a virus, a minute, filterable microorganism, distinctly visible under the microscope. This virus existed constantly in the central nervous organs and upon the mucous membrane of the nose and throat and of the intestines in persons suffering from the disease; it occurred less frequently in the other internal organs, and had not been detected in the blood of patients.

Although the microorganism of infantile paralysis was now known, the difficulties attending its artificial cultivation and identification under the microscope were such as to make futile the employment of ordinary bacteriological tests for its detection. Nevertheless, the virus could be detected by inoculation tests upon monkeys, as these animals acquired a disease corresponding to infantile paralysis in human beings. In this manner it had been determined that the mucous membrane of the nose and throat of healthy persons who had been in intimate contact with acute cases of infantile paralysis might become contaminated with the virus, and that such contaminated persons, without falling ill themselves, might convey the infection to other persons, chiefly children, in whom the disease developed.

The virus had, apparently, an identical distribution, irrespective of the types or severity of cases of infantile paralysis. There were so called abortive forms of the disease, in which definite paralysis of the muscles did not occur at all, or was so slight and fleeting as often to escape detection; the meningeal forms in which the symptoms resembled those of acute meningitis with which muscular paralysis might or might not be associated; and the familiar paralytic condition.

Microorganisms which conveyed disease escaped from the body of an infected individual in a manner enabling them to enter and multiply within fresh or uninfected individuals and cause further disease. The virus of infantile paralysis was known to leave the infected human body in the secretions of the nose, throat, and intestines. It also escaped from contaminated healthy persons in the secretions of the nose and throat. As the virus had never been detected in the blood of human beings, it was doubtful if biting insects could withdraw the virus from the blood of infected persons and reinoculate it in the blood of healthy persons.

The virus penetrated to the brain and spinal cord by way of the lymphatic channels after gaining entrance into the body by way of the upper respiratory mucous membrane. It was readily distributed by coughing, sneezing, kissing, and by means of fingers and articles contaminated with the secretion of the nose and throat. The virus withstood for a long time even the highest summer temperatures, complete drying, and even the action of weak chemicals, such as glycerin and carbolic acid, which destroyed ordinary bacteria. Its survival in the secretions was favored by weak daylight and darkness and hindered by bright daylight and sunshine. It was readily destroyed by exposure to sunlight.

The ordinary domestic fly might become contam-

inated with the virus contained in the secretions of the body and serve as the agent of its transportation to persons and to food with which they came into contact. Domestic flies experimentally contaminated with the virus remained infective for forty-eight hours or longer. So insects fell under suspicion as being potentially mechanical carriers of the virus of infantile paralysis.

Studies carried out in various countries where infantile paralysis had been epidemic, indicated that in extending from place to place the route taken was that of ordinary travel, by water or land, along a simple highway or the line of a railroad, thus connecting the distributing agency intimately with human beings and their activities.

The longest period after inoculation of monkeys in which the virus had been detected in the mucous membrane of the nose and throat was six months.

Not all epidemics of infantile paralysis were equally severe; there was great variation, not only in the number of cases, but also in the death rate. A factor of high importance was the infective power, or the virulence of the microorganism causing the disease, which fluctuated in intensity. Experiments had shown that by passing from monkey to monkey, the virus tended to acquire incredible activity.

Not all children and relatively few adults were susceptible to infantile paralysis, but young children were more susceptible than older ones. The light, or abortive cases indicated a greater general susceptibility than had always been recognized, and their discovery promised to have far reaching consequences in respect to the means employed to limit the spread or eradicate foci of the disease.

The period of incubation was subject to wide limits of fluctuation, being sometimes as short as two days, and sometimes lasting two weeks or longer; but the usual period did not exceed eight days. The period at which the danger of communication was greatest was during the very early and acute stage of the disease. However, this opinion was based on observation rather than on demonstration. Hence cases of infantile paralysis which had been kept under supervision for a period of six weeks from the onset of the symptoms, might be regarded as practically free from danger of infection to others. Infantile paralysis was one of the infectious diseases in which insusceptibility was conferred by one attack, including all the forms, namely the paralytic, meningeal, or abortive, all of which conferred immunity. This immunity rested on the presence of immunity bodies, whose presence in the patient had been detected twenty years after recovery from infantile paralysis.

Experiments in protective inoculation to produce immunity had been unsuccessful, though in some instances, in animals, protection was accomplished and the immunity bodies appeared in the blood. Passively transferred immunity bodies also persisted in the blood, but only for a brief time.

A measure of success had been achieved in the experimental serum treatment of inoculated monkeys. For this purpose blood serum derived either from recovered and protected monkeys and human beings had been employed. The serum was injected into the membranes about the spinal cord, and the virus was inoculated into the brain. The injection of serum was repeated several times in order to be effective. Unfortunately, the quantity of the human immune serum was extremely limited and no animals other than monkeys seemed capable of yielding an immune serum, while the monkey was not a practicable animal from which to obtain supplies.

As the virus of infantile paralysis attacked and attached itself to the central nervous organs, it was reached not only with difficulty, but it had to be counteracted with substances and in a manner that would not themselves injure those sensitive parts. The ideal means to accomplish this purpose was through the employment of an immune serum. The only drug that had shown any useful degree of activity was hexamethylenamine, which was germicidal and had the merit of entering the membranes as well as the substance of the spinal cord and brain. But experiments on monkeys had shown this chemical to be effective only very early in the course of the inoculation and only in a part of the animals treated.

During the prevalence of an epidemic, habits of self denial, care and cleanliness, and consideration for the public welfare could be made to go very far in limiting its spread. The conditions which obtained in a household in which a mother waited on the sick child and attended the other children were directly contrasted with those existing in a well ordered hospital; the one was a menace, the other a protection to the community. All objectionable household insects should be exterminated. Food should not be exposed in shops and food for sale to the general public should not be handled. Protection to the public could be best secured through the discovery and isolation of those ill of the disease and the sanitary control of those persons who had associated with the sick and whose business called them away from home. In the event of doubtful diagnosis, the aid of the laboratory should be sought, since even in the mildest cases changes had been detected in the cerebrospinal fluid removed by lumbar puncture.

A percentage of persons died during the acute stage of the disease, and this varied from five to twenty; the average death rate of many epidemics had been below ten per cent. Of those who survived, a part made complete recoveries in which no crippling whatever remained. The remainder suffered some degree of permanent crippling; in some so small a degree as not seriously to hamper the life activities of the individual; in others it might be minimized or relieved by suitable orthopedic treatment. But even a severely paralyzed child who had made little recovery of function by the time the acute stage of the disease was over might go on gaining for weeks, months, or years, and in the end regain a large part of his losses.

There was at present no safe method of preventive inoculation or vaccination and no practicable method of specific treatment. The prevention of the disease must be accomplished through general sanitary means; recovery from the disease was a spontaneous process which could be greatly assisted by proper medical and surgical care.

Dietetics, Alimentation, and Metabolism

Food and Food Preparation, in Health and Disease

FOOD, DRUGS, AND LONGEVITY.

Some Thoughts on Their Relations,

By Leroy D. Swingle, Ph. D.,
Department of Pharmacology, University of Utah.

(*Continued from page 75.*)

It has been stated by eminent authorities that "death is inherent in the somatoplasm" while the "germplasm is potentially eternal." This could not necessarily be true, unless in the process of development all the properties of life were thrown to the germplasm. Yet we know that the germplasm, even in the highest animal, man, does not appropriate all the properties of life at the expense of the somatoplasm, for the latter lives on often for 100 years. Death is no more inherent in the somatoplasm than in the germplasm, from which it develops by a genetic process of cell division. We believe rather that *life is inherent in all protoplasm,* differentiating it from dead matter. Death, we believe, results because the organism is imperfect, owing primarily to an indirect impairment which has come hereditarily through the action of an unfavorable environment and imperfect food upon the germplasm, and secondarily to a direct action of unfavorable environment and imperfect food upon the somatoplasm.

Why, then, does the germplasm live on, while the somatoplasm dies? Because the germplasm produces the somatoplasm, instead of the somatoplasm the germplasm, and because the somatoplasm gets a double dose of adverse environment and imperfect food. If the germplasm was budded off from the somatoplasm after it (somatoplasm) had reached maturity, it would probably be so damaged that it would not live long. The somatoplasm gets the double dose of adverse environment and imperfect food, because it is highly differentiated to perform the functions necessary to its own existence as well as the functions of nutrition and protection for the germplasm, while the germplasm lies dormant and undifferentiated. Being dormant it requires very little food compared with the active somatoplasm which must keep up by constant functioning a favorable environment for the germplasm, maintaining itself also as a buffer between the germplasm and an external unfavorable environment. This composite functioning—locomotion, digestion, respiration, excretion, etc.—which the somatoplasm must carry on both for its own existence and the life of the germplasm, requires large quantities of various food elements. While the somatoplasm has within itself certain powers of protection against injurious environment and unsuitable food materials, yet it is more directly exposed to them than the germplasm. Moreover, since its very existence depends upon a constant activity of its vital organs and a working correlation of their complex functions, its life is much less certain than it would be if it could live on in an undifferentiated condition. These two things, then, the constant direct contact with unfavorable conditions and a high differentiation, requiring a good supply of carefully balanced rations and a constant exercise and correlation of many delicate and complex functions, render continued life for the somatoplasm much more uncertain than for the undifferentiated, dormant germplasm. In fact, the perils under these conditions are so great that on their account alone, and not as a result of bad heredity, a large proportion of individuals lose their lives even before they reach sexual maturity, although their germplasm may be as good, or even better than the average.

Personifying the germplasm, it might be conceived as extremely selfish, maintaining its long life by inhabiting the somatoplasm, making it serve as a protection, a bodyguard, a slave. In order that its own life may be preserved, it takes its leave, abandoning its somatoplasmic slave to death. This takes place fifty or seventy-five years before death is certain to overtake the servant and destroy both. It means that the germplasm insures its own life somewhat like the bandit, Villa. He organizes a band of soldiers, and uses them as a guard and as servants to secure food and plunder for his gratification. He allows them to stand between him and the enemy. When he has obtained the maximum from this company he slips out before his opportunity of escape is menaced by the destruction of the band, and organizes a new one. Thus he allows his men to be sacrificed, while he continues his selfish life, outliving many bands. In a similar manner the germplasm outlives many generations of somatoplasm.

In view of these conditions, the fact that the somatoplasm comes in direct contact with environment, and the fact that it possesses a high differentiation necessitating a constant supply of delicately balanced rations, we arrive at the previous conclusion, namely, that the length of life of the somatoplasm may be increased by rendering the environment and the food supply more nearly perfect. Since our line of argument indicates that these conditions, rather than death inherent in the somatoplasm, explain why the somatoplasm does not live on like the germplasm, the improvement of the environment and the food conditions of the somatoplasm place it in a condition more nearly equivalent to that of the protected and undifferentiated germplasm, to which condition its greater length of life is to be ascribed.

What has been said constitutes a foundation for a more particular discussion of the relation of food and drugs to the longevity of the soma or individual.

There are two ways in which food and drugs may affect the length of life of the individual. They are: First, by directly influencing the somatoplasm which receives them, and, secondly, by affecting its germplasm, and through it, the somatoplasm of the succeeding generations. This means that the doctor must be a physician both of the somatoplasm and the germplasm.

At this point we would introduce certain matters relating more directly to medical practice. It is to be regretted that many doctors "practise medicine," in the primary sense of the term, when they should practise prophylaxis and therapeutics. The practice of medicine suggests the use of medicines (drugs) only. Yet the physician must use, not only drugs for the curing of disease, but among other things, dietetics for both the cure and prevention of disease. We cannot believe that drugs are a panacea for human ills and the prevention of death, though many of the patent medicine advertisers often assert as much. It is hard to believe that the physician would be influenced by such advertisements, nevertheless, from their frequent prescription of such drugs, we are led to conclude that an impression is made by the constant presence of such assertions before their eyes. However, the modern doctor who has had training in experimental pharmacology surely ought to escape any such influence. But, on the other hand, as he observes in the laboratory the marvelous changes drugs may produce in the functions of various organs, is he not apt to develop an inordinate confidence in drugs as therapeutic agents? Certainly he will not fall into the drug nihilist class, rather tending to go to the opposite extreme of relying upon drugs to a partial neglect of more natural means of prevention and treatment, such for example, as dietetics. In this reference to drugs, I do not necessarily include such agents as the glandular extracts, which might be considered as natural means, especially when their administration is not for an emergency. Still, even in the case of these agents, the indication for their use in conditions where they are not properly secreted, may yet be found to be necessitated primarily by improper food conditions.

The irrational treatment of many diseases, with drugs, without a proper regard for dietetics, paves the road from the patient to the egotistical, unscientific author of health series or of advertisements of health foods, who may advocate some truly valuable dietetic measures, but who fanatically, unconsciously, and dogmatically condemns truly valuable drug therapy. One of the best examples of such a violation of rational therapeutics is to be found in the doping of babies with drugs when the whole trouble is with the diet. Can anything but injury be expected, even though it may not result in obvious lesions? Some of the disorders of later life might be traceable, were our knowledge complete, to dietetic abuse during the early period of development. Not only may an unwise use of drugs be made to the neglect of natural dietetic means, but some may even recommend a diet which is known to be unsatisfactory, except possibly for a short period, and which will therefore bring on ill health. In a small western city the common practice in baby cases, where artificial feeding is necessary, is to tell the mother "just get a can of condensed milk and follow directions." This she does, and after using it for a couple of months or longer, she wonders why the baby is not doing well. Similar neglect occurs when the physician unscientifically prescribes proprietary foods, or leaves the mother to follow the ridiculous and conflicting advice of the neighbors who drop in, when she should have the advice that goes with scientific training. Truly these violations of the known principles of dietetics must have a direct effect, though silent and unobserved, upon the length of life of the victim, and possibly also upon his developing sex cells.

In speaking against the use of drugs when dietetics is indicated, it is not our intention to depreciate the value of drugs. The thought is that drugs cannot take the place of proper food. The body is an extremely complex laboratory with its different departments wonderfully correlated, and from the raw materials that come to it must be manufactured the numerous substances which are necessary to its automaticity and consequent existence as an organism. It must, therefore, make much difference, the kind, the form, and the quantity of raw materials supplied. If it asks a fish, should we give it a stone; if it calls for bread, should we give it mercury or opium? Yet this very thing is persistently done. Drugs play an indispensable role in therapeutics, but they cannot take the place of food. The rational use of drugs, based chiefly upon pharmacology and experimental therapeutics, is beyond criticism.

Drugs may act either by increasing or decreasing the functions of organs, but they do not change one function into another. For example, pilocarpine produces a greater flow of saliva from the salivary glands, but it does not cause contractile tissue to secrete. Nor will any other drug. To accomplish such a change in function, the drug would have to transform completely the histology of contractile tissue. Certain drugs will completely change the histology of the tissues, but when that is done, the tissues will not function in any manner; they are dead. The kind of function is determined by the morphological character of the tissue or organ, while the degree of function is measured by the chemical activity, and also, if it is a compound function, by the efficiency of correlation. It is these things that are generally modified by drugs administered in therapeutics, even though the drug itself may not enter into any chemical reactions. Although the drug may not produce a lesion or an *apparent* histological change in the tissues, which may completely destroy their function, and although it cannot induce a new function in an organ, and thus upset the balance of functions in the body, yet it may have harmful, remote effects as a result of increasing or diminishing certain functions. Many clear examples of such action might be cited, while other unknown slight effects may exist. Normally all the organs should balance each other in their functions. It would appear that a prolonged use of drugs, which, while bringing nearer to the normal the functions of a deranged organ, may render abnormal the functions of other organs and so upset the balance of functions, might allow the barriers against death to be thrown down earlier than otherwise. Many of the active drugs—and those are the only ones that could possibly have any value—used so extensively in this age of experimental medicine are known to have such untoward effects. Do we appreciate or fully know the ultimate end of these effects? Yet, if the function of the organ to

be treated is of more vital importance than the function of the organ which is affected unfavorably, the treatment with the drug may result in a net benefit. But the treatment with drugs generally would not remove the cause of the derangement of the organ, and so how much better it is to use a treatment that would strike at the cause of the abnormality without affecting the normal functions of other organs! In some cases it is certain that dietetics is that other treatment. As investigation proceeds, it will doubtless reveal a direct or indirect relation between other pathological conditions and the diet, so that the treatment of these conditions will become a natural one—dietetic. All will agree that drug therapy is not generally a natural treatment. Let us take the case of asthma caused by a spasm of the muscles of the bronchioles. Atropine, by paralyzing the myoneural junction and thus preventing the passage of nerve impulses to the muscles, may relieve the paroxysm. Nevertheless, the attacks may recur regularly. Atropine is merely palliative. In absence of knowledge or anything better, it might be considered a rational treatment, but it is not a natural treatment. Such a treatment is one that would attack the cause and not only remove the attack, but act as a prophylactic against recurrence. Asthma is a disease that may be due to anaphylaxis, and hence be caused by improper food conditions. Take the disease, diabetes mellitus. Death may be warded off by reducing the acidosis by the injection of large quantities of sodium bicarbonate. This, however, cannot affect the real cause of the disease, though it may temporarily remove the condition. Fasting is held to be beneficial, and hence there may be a causal relation between this disease and food conditions. If so, the natural treatment and prophylaxis would be a proper regulation of diet. This treatment could not be administered without a knowledge of the specific requirements of the individual. Is it possible that food requirements are specific for each individual?

Our point, then, is that drug therapy, while it may be beneficial and even ideal in certain conditions, may in other conditions have ultimate bad effects, because it is not generally a natural treatment. In seeking to avert disease and increase the longevity of the somatoplasm, the more sanguine outlook is along the line of dietetic investigations, rather than pharmacology. An apt illustration of this is to be found in the disease, beriberi. The cause of the disease is found to be the eating of polished rice without a sufficient amount of other kinds of food. Polished rice lacks certain obscure substances called vitamines which are necessary to proper function. It was once thought that the cause of the disease must be a protozoan parasite, and from such a viewpoint the treatment with sterilizing drugs was naturally indicated. The cause having been discovered to be improper food, treatment with drugs is plainly unnatural, even though they may be beneficial.

The practical import to the physician of this line of argument is for him not to be content with drug therapy, but to study the food conditions, especially in relation to diseases which are not known to be due to infections.

(To be continued.)

Diet of the Growing Child.—F. D. Strickler (*Medical Sentinel*, June, 1916) says that problems of of digestion, metabolism, nutrition, and growth present an almost endless task to the investigator. The primary fact in feeding the young is that the food consumed has not only to nourish the tissues, but to provide for future growth. Nutrition can only give the growth impulse free play; neither can succeed without the other, but while the former is controllable, the latter is not wholly subject to regulation at will. The feeding of a growing child is not a simple matter of calories, proteins, fats, carbohydrates, and inorganic salts; there is no doubt that the food needs of the growing organism are specific and peculiar. Growth is the manufacture of additional quantities of living matter. Protein in constant supply is necessary for the maintenance of life—fats and carbohydrates being subsidiary—and is the main constituent of protoplasm, but in what form it exists there is unknown. In the light of recent studies, food products do not enter into metabolism unchanged, or slightly altered, the end products of digestion are not peptones or proteoses, but these are further changed by hydrolytic cleavage into simpler crystalline bodies or aminoacids, which assume an increasing importance in the problems connected with nitrogenous metabolism. It is probable that the purpose of protein digestion is to reduce the complex molecule of protein to the form of crystalline products, the absorption of which is normal. The nutritive value of any protein is the character and extent of the aminoacid it contains, of which eighteen are known at present. All proteins do not promote growth under otherwise favorable conditions, and in the absence of lysin the construction of new tissue does not take place readily, or at least proceed at the normal rate. The results of experiments lead us to believe that lysin is indispensable for growth, and therefore that it forms an important part of the diet of the growing child. Proteins like casein, lactalbumin, and egg vitellin, which are in nature concerned with growth, have a relatively high content of lysin. Milk, eggs, beef, mutton, and halibut are foods that contain lysin in relatively large quantities, and should therefore form an indispensable part of the diet of the growing child. Corn, rye, barley, and rice are relatively poor in lysin and should be avoided as an exclusive diet.

The absolute necessity of fats as promoters of growth lacks conclusive evidence. They are absorbed as fatty acids and glycerin, but while they serve as a source of energy, they are not as efficient as carbohydrates as protein sparers. Butter fat, egg yolk, and codliver oil promote growth, though their nutritive value seems to be due, not to the fat, but to some accessory diet factor. It is now recognized that there is a specific requisite for growth, which is known as growth vitamine, the exact nature of which is unknown, although it is found in milk, egg yolk, and codliver oil. Butter fat and codliver oil will not produce growth unless they are combined with a proper proportion of inorganic salts, suitable carbohydrates, and specific protein. These facts give a rational basis for the feeding of the growing child, whose diet should contain a liberal amount of milk products, eggs, and meat in order to stimulate or promote normal growth.

THE DUCTLESS GLANDS AND MALIGNANT GROWTHS.

Whatever the exciting cause of malignant growths may be, there is no question that the predisposing factors reside in the body of the affected individual, and are in all probability associated with metabolism. It is natural, therefore, that investigators should turn their attention to the influence of certain foods and more particularly to the effect of the ductless glands. The effect of meat, vegetables, salt, and other food stuffs on the predisposition to cancer has been investigated by a number of authors with, however, conflicting results. Yet the very fact that in experimental sarcoma, the administration of certain food stuffs had a marked influence on the susceptibility of the animal to inoculation, is of great significance. The experiments of Negre showed a lessened susceptibility to experimental cancer in mice fed for long periods on food to which table salt was added. The salts of potassium, on the other hand, increased susceptibility.

This latter observation was confirmed by a number of investigators. The salts of calcium and barium diminished susceptibility in the experiments of Rosenthal and Goldzieher. Decreased susceptibility to sarcoma in rats and chicks fed on polished rice was observed by Funk, while Danysz and Skrzynsky found an increased susceptibility in animals fed exclusively on vegetables. Similar observations carried on with different foods by a number of investigators, showed undoubtedly that certain foods diminish while others increase the susceptibility of the animal to experimental cancer or sarcoma.

Broadly speaking, a malignant growth may be regarded from two standpoints: First, a sudden tendency to localized formation of new tissue, a sort of perverted parthenogenesis; and, second, a lowered resistance on the part of the surrounding tissue to the invasion of the new growth. Both these phenomena must be influenced by the metabolic activities of the cells concerned in the process. This being the case, it is not astonishing that the ductless glands with their secretions and hormones should exert such an influence to a marked degree; and this is borne out by a large number of clinical observations and experiments by various authors.

Recently, Korentchevsky (*Roussky Vratch*, February 6, 1916) has contributed a lengthy article on the subject, recording his experiments on animals inoculated with sarcoma. In one series, dogs were either castrated or subjected to thyroidectomy, or both. In this series it was noticed that the largest number of successful inoculations as well as the largest growths were obtained in animals that were either castrated or had had their thyroids removed. Those on which both operations were performed showed greater resistance to the new growth. In these animals the growth underwent retrogression much more quickly than in the controls or in those which were either castrated or thyroidectomized. In another series of experiments, rats were inoculated with sarcoma, and received then varying doses of ovarian extract, luetin, and autolysin. Not only was the growth of the tumor inhibited, but in many cases, when small doses were employed, the growth disappeared altogether.

In still another series of experiments, the spleen was removed, either alone or together with the reproductive glands. In all these cases the susceptibility to the formation of sarcoma was increased and the tumor itself grew larger, the effect being more marked when the spleen alone was removed. In another series, the administration of thyroid extract, notably in small doses, inhibited the growth of the tumor.

The conclusions drawn from these experiments by the author are interesting. He maintains that the sex glands, the thyroid, the thymus, and the

spleen, contain substances which inhibit the development of malignant growths, and furthermore, this inhibition may be obtained by the internal administration of dried extracts of glands. The evidence seems conclusive that the ductless glands play a very important role in the production as well as the growth of tumors, and further investigations may not only throw light on this phase of the etiology of cancer, but show the way to a more successful therapeutics.

THE DIAGNOSIS OF SYPHILITIC PHLEBITIS.

To corroborate a diagnosis of early luetic phlebitis, a methodical examination of the limbs of syphilitic subjects who present primary and secondary lesions must be made. When, in a syphilitic presenting cutaneous or mucous lesions, an indurated cord following the anatomical course of the superficial veins of a limb is detected, a specific phlebitis is evident and diagnosis becomes an easy matter.

Mistakes are possible, particularly when the secondary accidents are so mild as to escape notice, while on the other hand a patient is more than likely to avoid mention of former specific affection. The torpid type, without rise in temperature, undergoing evolution in from six to eight weeks, without complications, but with a decided tendency to diffusion, relapses, or perhaps spontaneous resolution may enlighten the diagnosis.

It is more difficult to make a diagnosis between a phlebitis and lymphangitis of luetic origin, because the latter lesion produces a superficial cord, sometimes painful and accompanied by red cutaneous lines, but a knowledge of the anatomical course of the veins and the results obtained by compression of the limb over the indurated cord, will furnish clues.

In spite of the evidence offered by these means, mistakes have been frequent. The diagnosis is made in conditions quite different when, as in certain cases of early luetic phlebitis, particularly in the later types, the physician discovers a limb to be the seat of a white, painful edema with a collateral circulation. Under the circumstances a diffuse phlegmon may be suspected, but the redness, blisters, and swelling *en masse* of the entire region involved, give the limb an entirely different aspect. Then, too, palpation does not reveal a deep seated induration along the venous tract, while the general symptoms are much more evident in phlegmon.

In some cases the diagnosis of arteritis has been made. The absence of pulsation, the lowered temperature of the limb, and a tendency to gangrene should at once prevent the diagnosis of phlebitis. Coexistence of the vascular lesions has been recorded, however, e. g., a syphilitic obliterating phlebitis and arteritis of the popliteal vessels. In this case the arteritis had been diagnosticated, but the phlebitis was discovered only after microscopical examination of the specimen.

In considering the diagnosis it becomes evident that the gouty and rheumatic forms of phlebitis need not be considered, as their etiology will be evident. In difficult cases it is merely a question of recalling that luetic phlebitis is to be encountered, and that when a case presents itself in which the diagnosis is not quite clear, the Wassermann reaction or specific treatment will indicate the correct diagnosis.

ALCOHOL AS A PUBLIC HEALTH PROBLEM.

Significant of a changed attitude toward the use of alcohol on the part of the medical profession is the announced policy of the New York board of health which is attacking this problem from the standpoint of the public welfare. This policy is thus outlined (*Bulletin*, February 19, 1916): "The department of health has no sympathy with and will take no part in legislative or police restrictions or attempts to limit personal liberty in the use of alcoholic beverages. The spread of accurate information among the people as to the effects of alcohol can be depended upon to accomplish more than laws restricting its manufacture or sale. In the long run compulsory prohibition will not prohibit until the public is ready to cease using alcohol, when restrictive laws will be superfluous."

In pursuit of this policy a recent bulletin of the department presents two timely papers in popular style. The first is on the sociological aspects of the alcohol question, by Donald B. Armstrong, director of the department of social welfare of the New York Association for Improving the Condition of the Poor. After reviewing the actual knowledge available of alcohol and its effects, Armstrong summarizes the arguments against its use under the indictments that it is a disease producer, both direct and indirect, that it is a vice and crime promoter, that it is a factor in economic waste. To meet these indications for action against alcohol, he recommends, first, a realization of the facts regarding alcohol with a careful avoidance of overstatement and prejudice; second, the radical and ultimate control of the problem by national prohibition of the manufacture and importation of alcohol; third, public education; fourth, the realization of the social point of view, recognizing the fact that the good of society as a whole is greater than the preference of its individuals and that society has

an obligation for the success of a "social program involving a more efficient social organization, the elimination of unnecessary human waste, and the provision of an environment which will make it possible for every individual to serve as best he may."

The second paper referred to is on life insurance and drinking habits, by Arthur Hunter, actuary of an important life insurance company. After reviewing the experience and statistics of a number of the large insurance companies in regard to the effect of alcohol on the insurance value of persons using it in varying degrees, Hunter concludes from the opinions of the medical directors that insurance companies do not favor applications from persons who drink freely, even though not to the point of intoxication, nor applications from those who formerly drank heavily but have stopped. Statistics prove that a higher rate of mortality is to be expected in those using alcohol, and that the rate is proportional more or less to the amount of alcohol consumed. He cites the experience of seven of the large American companies, which shows that abstainers have from ten to thirty per cent. lower mortality than nonabstainers. In short, it is conclusively shown that alcohol has an unfavorable effect on longevity and that total abstention materially increases longevity.

The course laid out by the New York health department, to consider the use of alcohol along educational lines, as a public health problem, might well be imitated by other health organizations as well as by private concerns.

THE PREMATURE BURIAL OF BABIES.

When the effort of the narrator is to portray the acme of horror, a tale of premature burial has ever been a favorite. Poe even says that such tales "are too entirely horrible for the purpose of legitimate fiction. . . . To be buried while alive, is, beyond question, the most terrific of these extremes (of agony) which has ever fallen to the lot of mere mortality." The intense suffering attendant upon such a fate is more mental than physical, depending upon the realization of the hopelessness of the situation. This physical horror obviously cannot be present in the case of infants, which is perhaps why the possibility of their premature burial has not received as much attention as the same accident to adults.

An Italian writer, Professor Baculo (*Giorn. internaz. d. sci. med.*, XXXVII, 625, 1915) has lately called attention to a case of his own where a two months old child was for a half hour in a state of suspended animation, closely counterfeiting death. He cites various causes of sudden death in infants which may produce such a condition, diseases of the endocrinous glands for example. Many physical signs exist, such as the depletion of the retinal arteries and the invisibility of the optic disc. There is also Icard's method of the subcutaneous injection of fluorescein solution, which will turn the conjunctiva yellow and the skin green if the patient is still alive.

It would seem that in any institution where death occurs frequently and these delicate tests are not a matter of routine, there should be some safeguard against premature burial; not perhaps such an elaborate system as was formulated by the hero of Poe's story, but one more in the nature of the suggestion put forward by Baculo. The principle of this is a lever in contact with the sternum, any movement of which makes an electrical contact and causes a bell to ring. This is certainly better than the practice of piercing the heart with a needle, which is now and then made an ante mortem request.

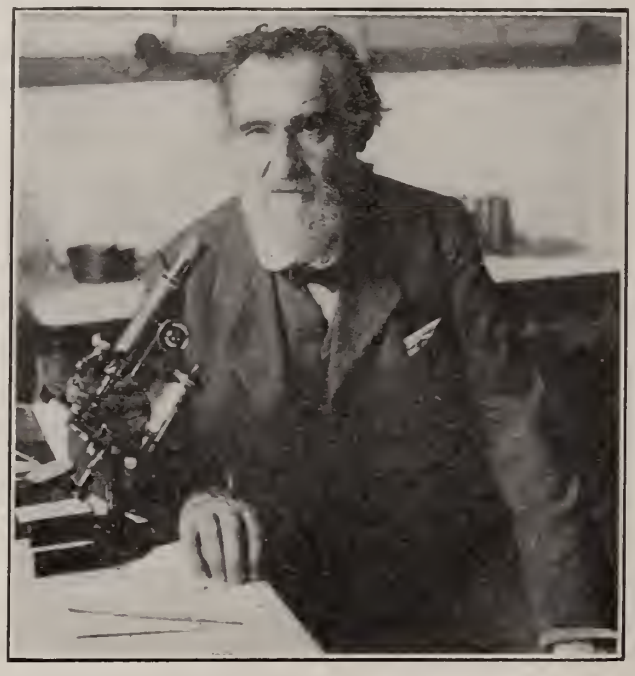
THE ROENTGEN RAY IN DIAGNOSIS.

Considered at first to be merely of academic interest, the Röntgen ray has been gaining favor steadily as an aid to diagnosis. Its earliest use was to ascertain the presence or absence of a fracture. As machines then could not deliver much energy, the lack of power had to be made up for by long exposure, and this weakness in a way led to many unfortunate results to both operator and patient. Of the pioneers who blazed the way, some gave up their lives and so taught those who followed how to protect themselves. As time passed, many improvements were made in both machines and tubes, and operators acquired greater skill. As more power became available, the time of exposures for plates was decreased, and on account of the greater penetration thicker portions of the body could be examined with satisfactory results.

Then, too, more accurate methods of measuring the rays were elaborated until it became possible to regulate the amount of energy employed and by so doing to obtain röntgenographs even of soft tissues of varying density. In the past few years great advances have been made in diagnosis; methods are employed every day that until recently were unheard of. Probably the first field in which modern methods became useful was the gastrointestinal. The discovery that insoluble salts of the heavy metals could be used in test meals and colon injections gave a wonderful impetus. The early diagnosis of cancer or of gastric ulcer soon became an accepted fact, and today the Röntgen ray examination has become almost a routine procedure.

Yet it is by no means in abdominal cases only that so much has been accomplished. Many thoracic conditions are being revealed to the eye that heretofore were either guessed at or remained unrecognized. Lesions of the heart, aneurysms, calcified aortas, mediastinal tumors, abscesses of the lung, and tuberculosis, both in its early and late stages, are now diagnosed; cerebral conditions and changes in the bones themselves are rendered visible.

Although the röntgenograph is most useful and even indispensable in many instances, there is little doubt that the fluoroscope is being relied upon more and more. The examiner can get much information that otherwise could be obtained only by taking innumerable plates. He can get views from many different angles and in that way receive an impression of the case that otherwise could not be procured. Like many another laboratory product, the Röntgen ray has reached a stage where its use is considered essential to the proper practice of medicine. A physician may make a diagnosis of syphilis without having a Wassermann made, or he may make a diagnosis of cancer or ulcer of the stomach without a Röntgen ray examination, but in neither case will the diagnosis be as accurate and satisfactory as if he had had use of all the means at his disposal.



THE LATE PROFESSOR METCHNIKOFF.

Obituary

ELIE METCHNIKOFF, M. D.,
of Paris, France.

Professor Metchnikoff died on July 15th in an apartment of the Pasteur Institute, Paris. He was born in 1845 in Kharkov, Russia, where he began his studies. These were continued in a Russian university and in Giessen and Munich, until 1870, when he was appointed professor of zoology in Petrograd and Odessa. In 1882 he resigned, and while studying along the shores of the Mediterranean, formulated his theory of inflammation and announced his discovery of the role of the leucocytes in disease. Metchnikoff succeeded the founder of the Pasteur Institute as director in 1895, and began his studies of longevity. In 1909 he promulgated his famous theories on the proper length of life for human beings, having decided from investigation in the Balkan country that the extensive use of sour milk as a beverage was the secret of the numerous centenarians living in that region. His book on the subject was of a mystical cast, however, and his thesis was bolstered up by quotations from the Bible. As we pointed out at the time, he misinterpreted the peculiar antiphonal nature of the *Psalms* in order to be able to cite them in support of his ideas. He was called an atheist; but in a Roman Catholic country, as France is supposed to be, this often means no more than continued absence from church services. In 1912, he announced his discovery of the glycobacter in the intestine of the dog, the inoculation of which into the human being he believed would go farther than sour milk in the prevention of senile breakdown. These theories concerning long life may be said to be still on trial. Later on, Metchnikoff announced a cure for diabetes and a theory concerning cancer, which he attributed to a microbe. In 1915, on his seventieth birthday, he received a "golden book" autographed by famous coworkers. His published works include *The Nature of Man, Immunity in Infective Diseases, Prolongation of Human Life,* and *Optimistic Essays.* In 1908, he divided the Nobel Prize for medical research with the late Dr. Paul Ehrlich; despite his poverty, he devoted the $20,000 received to scientific work. There is no doubt that he owed much of his success to his quenchless enthusiasm.

News Items

A Base Hospital Unit at the German Hospital, in New York, is being organized under the American Red Cross Society. Its director is Dr. Frederick Kammerer, who has just withdrawn from active service with the medical corps of the German army, and brings to his task the valuable knowledge gained at the German front in the European war zone.

Personal.—Dr. Thomas A. Storey, director of physical training in the College of the City of New York, has been appointed State inspector for physical training of the Military Training Commission for New York State.

Mr. Hugh M. Foster, son of the late Dr. Frank P. Foster, for many years editor of the New York Medical Journal, has been appointed secretary to Dr. Haven Emerson, commissioner of health for the city of New York.

Dr. William H. Welch, professor of pathology at Johns Hopkins University, Baltimore, has received the honorary degree of doctor of laws from the University of Chicago.

A Directory of City Health Officers.—The United States Public Health Service recently sent to the health department of every city in the United States having a population of 10,000 and over in 1910, blank forms requesting the name and official title of its health officer. The information obtained constitutes a fairly complete directory of city health officers throughout the United States. It is published in the June 30th issue of *Public Health Reports*.

Merger of Philadelphia Medical Schools Postponed.—Announcement is made that the members of the United Medical Committee in charge of the administration of the medical department of the University of Pennsylvania and the Jefferson Medical College of Philadelphia have agreed that it is advisable to postpone the consummation of the union agreed upon by the trustees of the two institutions, in order that further opportunity may be afforded for considering a number of important matters relative to the mode of administration of the new school. The schools will be conducted separately, therefore, during the college year, 1916-1917.

Medical Preparedness League.—This is an organization whose interest in military medicine is that which pertains solely to the betterment of the United States in times of peace and medical efficiency in times of war. The object of the league is to make instruction in military medical matters available to the practising physician whose duties and ties are such that he cannot devote the necessary time to camps of instruction. It has for its headquarters Room 416, St. Francis Hotel, San Francisco. Dr. Benjamin Jablons is chairman, Dr. W. S. Johnson secretary, and the following are honorary members: Dr. P. K. Brown, Dr. J. H. Graves, Dr. W. S. Graves, and Dr. Harry M. Sherman. Those who are interested in the work of the league should communicate with the secretary for further particulars. There are no monetary obligations involved in membership.

Mental Dispensaries in Michigan Advocated.—In an address delivered at a conference of the superintendents and trustees of Michigan State Hospitals, held in Kalamazoo, Thursday, July 20th, Mr. George A. Hastings, executive secretary of the Committee on Mental Hygiene of the State Charities Aid Association of New York, advocated the establishment in Michigan of a statewide system of free dispensaries for the earlier discovery and treatment of mental disease, similar to those operated in connection with State hospitals in New York. Mr. Hastings pointed out that the clinics in New York had informed the people more adequately about the nature, cause, and prevention of mental diseases and established a more intelligent public attitude toward such disorders. He said that State hospitals would reach their greatest value and usefulness when they gained the confidence and understanding of the districts which they served, and he believed that by means of such dispensaries and broader educational work the State hospitals would become centres of mental health as well as places for care and treatment.

American Electrotherapeutic Association.—The annual meeting of this society will be held in New York, September 12th, 13th, and 14th, with headquarters at the Hotel Martinique. Dr. Jefferson D. Gibson, of Denver, Colo., is president of the society, and other officers are as follows: Vice-presidents, Dr. J. Willard Travell, of New York, Dr. Frank B. Granger, of Boston, Dr. William L. Clark, of Philadelphia, Dr. Sidney A. Twinch, of Newark, N. J., and Dr. William Martin, of Atlantic City, N. J.; treasurer, Dr. Emil Heuel, of New York; secretary, Dr. Byron Sprague Price, of New York; registrar, Dr. Frederick M. Law, of New York. Board of trustees: One year, Dr. Charles Rea Dickson, of Toronto, and Dr. Edward C. Titus, of New York; two years, Dr. George E. Pfahler, of Philadelphia, and Dr. Frederic de Kraft, of New York; three years, Dr. Frederick Harris Morse, of Boston, and Dr. John W. Torbett, of Marlin, Texas. Complete programs and further information regarding the meeting may be obtained from the secretary, 65 Central Park West, New York.

Workmen's Compensation and Tuberculosis.—The New York workmen's compensation law provides for compensation for "accidental injuries arising out of and in the course of employment and such disease or infection as may naturally and unavoidably result therefrom." A workman in the State of New York jumped into a river to save himself when a timber broke. He "contracted a heavy cold and pleurisy, which developed into tuberculosis." The New York Industrial Commission awarded compensation to the workman, and the State Supreme Court affirmed the award. The opinion is published in the June 30th issue of *Public Health Reports*, page 1719.

A Hospital Ship Torpedoed in the Black Sea.—National Headquarters of the American Red Cross in Washington have just received a cablegram from the Central Committee of the Russian Red Cross in Petrograd, stating that on July 8th the hospital ship *Vperiod* of the Russian Red Cross, having all the external marks required by The Hague Convention, was torpedoed and sunk about thirty-two leagues from Batum near the village of Vitse, on the Black Sea, by an enemy submarine. There were eight deaths and seven wounded among the crew and sanitary personnel of the ship. All hostile governments had been notified of the equipment of the *Vperiod* as a hospital ship, and the possibility of a mistake is excluded.

Appointments and Promotions at the Rockefeller Institute.—The Board of Scientific Directors of the Rockefeller Institute for Medical Research announces the following promotions and appointments: Dr. Alphonse R. Dochez, hitherto an associate in medicine, has been made an associate member. Dr. Henry T. Chickering has been appointed resident physician in the hospital, to succeed Doctor Dochez. The following have been made associates: Dr. Louise Pearce, pathology and bacteriology; Dr. Frederick L. Gates, pathology and bacteriology. The following have been made assistants: Dr. Oswald Robertson, pathology and bacteriology; Mr. Ernest Wildman, chemistry. The following new appointments have been made: Dr. Rhoda Erdmann, associate in the department of animal pathology; Dr. Rufus A. Morrison, assistant in medicine and assistant resident physician; Dr. John Northrop, assistant in the department of experimental biology; Dr. Jean Oliver, assistant in the department of pathology and bacteriology; Dr. Ernest W. Smillie, Fellow in the department of animal pathology; Dr. William D. Witherbee, assistant. Mr. Hardolph Wasteneys, hitherto an associate in the department of experimental biology, has accepted an appointment as associate professor of pharmacology in the University of California.

Clinical Lectures on Poliomyelitis.—The present epidemic of poliomyelitis affords an unparalleled opportunity for clinical study and observation. The department of health of the city of New York, through the cooperation of various hospitals which are treating a large number of cases of poliomyelitis, has arranged a series of clinical lectures open only to physicians, to be conducted by men who have had an unusual opportunity to study this disease. Physicians are cordially invited to attend any and all of these clinics and the department hopes that advantage will be taken of this exceptional opportunity to study the disease. These clinics are to be conducted during the week beginning Monday, July 24th, at the following hospitals: Willard Parker Hospital, Dr. Philip Van Ingen and associates, 4 to 5 p. m., Monday, Tuesday, Wednesday, Thursday, and Friday. Kingston Avenue Hospital, Dr. Louis Ager and associates, 4 to 5 p. m., Monday, Tuesday, Wednesday, Thursday, and Friday. Mount Sinai Hospital, Dr. Herman Schwarz, 4 to 5 p. m., Monday, Tuesday, Wednesday, Thursday, and Friday. Bellevue Hospital (Isolation pavilion, Ward 32), Dr. J. S. Ferguson, 4 to 5 p. m., Tuesday, Thursday, and Saturday. Babies' Hospital, Dr. Charles Gilmore Kerley, 4:30 to 5:30 p. m., Tuesday and Thursday. Swinburne Island (Quarantine Station), Dr. Frank Clark, 4 to 5 p. m., Thursday and Friday.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Twenty-ninth Communication.

PILOCARPINE.

The alkaloid, pilocarpine, has much the same kind of restricted use in provoking hidrosis as eserine has in the production of catharsis. Each is usually efficient for the purpose, but in the same drug field each has adequate competitors with less marked reactions, so that the more powerful drug is best reserved for grave emergencies.

On the central nervous system pilocarpine acts as a depressant affecting some of the lower centres only, the mental confusion and hebetude following toxic doses being largely secondary to the severe systemic exhaustion.

The chief action of pilocarpine is on glandular tissue and unstriped muscle, each of which it markedly stimulates by irritation of nerve terminals, thus acting like atropine, but with directly contrary effects. This selective activity results in a series of curious phenomena. Contraction of the bronchial muscles lessens pulmonic circulation, and thereby renders breathing slow and somewhat dyspneic. The heart is slowed (usually in lower animals) by direct action on the terminals of the vagus; although frequently in man there ensue acceleration and palpitation, the mode of induction of which is obscure, although reflexes from the intestinal tract probably exert some influence. The blood pressure is raised through action of the vasoconstrictors throughout the body.

Stimulation of the unstriped muscle receptors of the bowel produces an active or even violent peristalsis, similar to that brought on by physostigmine, soon resulting in copious, watery stools, colic, and tenesmus; this may be accompanied by nausea and vomiting, both as direct effect and as reflexes from the sharp intestinal irritation. This hydragogue effect is accentuated by the action which pilocarpine has on the secretory glands of the intestine, whereby a profuse secretion is promptly produced.

Other secretory glands are affected early, including the lacrymal, mucous, and ceruminous; but the most evident effect is on the salivary and sweat glands, which respond vigorously, the salivary glands giving a constant reaction, the sweat glands, however, not always responding.

There is increased leucocytosis, due probably to splenic stimulation, and considerable augmentation in the output of carbon dioxide.

These marked reactions of the system to the drug make the therapeutic utilization of pilocarpine questionable, for any desired result will be so complicated by attendant phenomena as readily to make the second condition of the patient worse than the first, especially if there is aroused a too severe intestinal reaction. As noted in the preamble, in most cases simpler drugs or means are nearly always at hand. Even in cases where a free sweat seems indicated, a minimum of depression will follow hot air treatment, and this is to be preferred to a maximum produced by pilocarpine. Yet there are grave emergencies, like acute cerebral congestion or uremic poisoning, where a quick acting depleting agent seems demanded, and in these cases no one drug seems so satisfactory in its temporary manifestations as pilocarpine. But the practitioner using it, shoulders the wholesome necessity of watching carefully the effects of the drug for some time. Fortunately, adverse symptoms, as well as therapeutic reactions, may be promptly controlled by the cautious use of atropine.

Treatment of Throat Inflammations.—Capitan (*Bulletin de l'Académie de médecine,* May 30, 1916) reports on 417 cases of throat inflammation observed and treated since the outbreak of the European war. The cases are grouped into, 1, those of simple angina, often that of scarlet fever, measles, or mumps, showing, upon bacteriological study, principally streptococci or staphylococci, 256 cases; 2, those of Vincent's angina, showing spirillar and fusiform organisms, forty-three cases, and, 3, those of diphtheritic angina, 118 cases. All these cases were in soldiers aged nineteen to forty-five years, and recovery took place in all. Stress is laid on the fact that a clinical differentiation between cases of the three groups referred to was only exceptionally possible. Each of the groups exhibited varying and identical appearances of the throat, ranging from erythema, with or without swelling, to the formation of a whitish, grayish, or yellowish, more or less thick and variously distributed exudate, with or without pain, glandular enlargements, edema of the tongue, uvula, or the peritonsillar tissues, paresis of the velum palati, fever, etc. Treatment, to be rational, must therefore be based on bacteriological study. Awaiting the bacteriological diagnosis, Capitan, in the first twenty-four hours, has the patient gargle with the following:

℞ Acidi salicylici, ... 50 grams;
Sodii boratis, ... 100 grams;
Aquæ, ... 1,000 grams.
Fiat solutio.

One half to one gram of quinine is given and a watery ten per cent. solution of collargol applied to the throat two or three times. If the general condition is poor the following stimulant is given:

℞ Sparteinæ sulphatis, ... 0.1 gram;
Extracti cinchonæ (Codex), ... 2 grams;
Alcoholis, }
Glycerini, } ..... āā 20 grams;
Aquæ, ... 100 grams.
Fiat solutio.

Treatment corresponding to one of the three groups of cases above mentioned is not undertaken unless the symptoms are grave and definitely suggestive of one of these groups. Next day, the bacteriological

diagnosis having been made, patients of the first group receive sodium salicylate internally and externally for pain, often with the tinctures of belladonna and aconite internally, and the ten per cent. collargol solution, or the following mixture of Moure applied to the throat three times a day:

℞ Zinci chloridi, ...3 grams;
Acidi hydrochlorici, ...1 drop;
Glycerini, ...30 grams;
Aquæ destillatæ, ...70 grams.
Fiat solutio.

Where the indication presents copious lavage of the throat with hydrogen peroxide solution diluted one in four, or a five per cent. solution of sodium borate is carried out.

In cases of Vincent's angina a ten per cent. solution of arsenobenzol with glycerin is applied two or three times daily in the depths of the ulcerations; in serious cases, pure arsenobenzol may be used with advantage. Healing uniformly follows, usually in from twelve to fifteen days. Mouth washings, gargles, cinchona, and sparteine are also administered, according to indications. Diphtheritic angina sometimes shows only local redness, some dysphagia, with or without fever or glandular enlargement. In these cases results from diphtheria antitoxin were practically nil. Treatment like that of simple angina, supplemented by the measures indicated for diphtheria carriers gave excellent results in these instances. In diphtheria with false membrane, however, Capitan always gives antitoxin in large doses. In diphtheria of intermediate severity he injects sixty c. c. of antitoxin in the abdominal wall and administers the sparteine-cinchona-alcohol combination, with the addition of four grams of calcium chloride, every day until the throat is completely free. Further daily injections of thirty to sixty c. c. of antitoxin are given, according to indications. Sometimes injections on the first two days are sufficient; the fifth injection is rarely required. On the average, 180 to 210 c. c. of serum are injected, in four days, the least being fifty c. c. and the most 270 c. c. All the author's cases ended in recovery. Where diphtheria bacilli persist after disappearance of the false membrane Capitan applied a ten per cent. solution of arsenobenzol with glycerin two or three times a day, with good results. Insufflations of powdered antidiphtheritic serum into the throat and nasal fossæ twice daily were also employed, with marked success, the carriers being rendered sterile in four to six days. The insufflations may be discontinued as soon as a negative culture is obtained.

Gunshot Fractures of the Femur.—E. W. Hey Groves (*British Journal of Surgery*, April, 1916) summarizes this subject as follows: The treatment of gunshot fractures of the femur requires the limb to be immobilized at the earliest moment, and that the immobilization shall not interfere with frequent dressings. This is best accomplished by a wire cradle sling splint constructed on the principles of the double inclined plane. When the wounds have been opened thoroughly and drained by judicious transverse incisions, and have taken on a healthy character, weight extension should be applied and maintained until union is firm. While weight extension may be applied by adhesive plaster or by transfixion, the latter is by far more trustworthy, but is attended by certain risks of septic infection of the soft tissues, and particularly of the knee joint. When treated according to the foregoing principles, the results are as follows: Loss of life, ten per cent.; loss of limb, 6.6 per cent.; good form and function in limbs saved, seventy-four per cent.; delayed union, sixteen per cent.; delayed healing, six per cent.; deformity, four per cent. The most important factor in the determination of the foregoing results is the presence and degree of sepsis. Comminution, apart from sepsis, is no hindrance, but rather a stimulus to rapid union; the removal of pieces of comminuted bone is unwarranted, and is the most potent cause of nonunion. While all types of metal sling splints may give good results, those which like the Thomas require a fixed ring round the thigh of the broken leg should only be used for transport, and then only if the wire cradle splint is not available, for the thigh ring becomes soiled by feces and wound discharges and is a source of great discomfort to the patient. While the Hodgen, the Balkan, and the wire cradle splint all are correct in their principle of holding the leg in a position of semiflexion of the hip and knee, only the last is self contained, and can be used for transport; furthermore, it gives greater facilities for massage and movements than the other. The position of flexion of the thigh entails the risk of encouraging pus to track up the limb, but this can be prevented by thorough opening of the infected area, or, if not prevented, it must be met by the use of a hinged splint which keeps the limb horizontal except for dressing, when it is elevated by a strut.

Treatment of Gunshot Wounds of the Chest.—J. L. Menzies (*British Journal of Surgery*, April, 1916) says that such wounds must be watched carefully from the time of injury. The immediate symptoms generally improve when the patient is kept quiet. Hemoptysis ceases spontaneously in nearly all cases. At the time of injury morphine may be given, and any bleeding from intercostal arteries should be arrested but, as a rule, no further treatment is necessary beyond keeping the patient quiet. On admission to hospital, when there is no effusion into the pleural cavity, no special treatment is necessary, and recovery is rapid. When effusion is present the chest should be explored at an early date and the fluid examined bacteriologically. If the fluid is found to be sterile, it may or may not be removed. In cases where the effusion is large, with marked dyspnea and much displacement of the mediastinum, it is always advisable to aspirate the fluid; but when the effusion is not large it may be aspirated or left alone, and when a hemothorax is found to be infected it should be aspirated or drained early. It was found in this series that resection of a portion of rib, and drainage by tube, gave most satisfactory results. When definite pus is present the pleural cavity should be drained at the earliest possible time by the resection of a portion of a rib and the insertion of a large drainage tube. Where a large empyema cavity exists, weak iodine body baths were found beneficial, or gentle lavage of the pleural cavity through a tube without pressure was employed.

Causation and Cure of Certain Forms of Lunacy.—Rupert Farrant (*Brit. Med. Jour.*, June 24, 1916) has made careful comparative studies on over 3,000 sections of the pituitary, pineal, thyroid and sexual glands from normal and insane persons and has come to certain conclusions regarding the relationship of these glands to some forms of insanity. All of these glands react to certain toxemias by hypertrophy and later by atrophy. Atrophy of the pineal, pituitary and thyroid were found in primary and secondary amentias, while in dementia præcox the alteration in these glands corresponded to the duration of the disease. Changes were found in the thyroid, pituitary and sexual glands in some cases of acute confusional insanity, melancholia, and manic depressive and other forms of insanity. Abnormality of the thyroid was frequent in insanity in children, adolescents and adults. Changes in the sexual organs were often found in association with altered mentality varying from mania to exhaustion psychosis. From these observations two forms of treatment are suggested: If there is hypertrophy and overactivity of one or more of these glands attempts should be made to locate the primary toxemia and cure it. This will most commonly be found to be in carious teeth and intestinal stasis. When there is atrophy of the glands their secretions should be artificially supplied, and good results should be expected from such treatment if undertaken before definite cortical brain lesions have developed.

The Process of Repair in Wounds of the Small Intestine.—John E. McWhorter, A. P. Stout, and Charles C. Lieb (*Surgery, Gynecology and Obstetrics*, July, 1916) summarize wound repair in small intestines thus: 1, The noninfected suture line in the small intestine in dogs was very resistant to internal hydrostatic pressure, for at one hour after operation and any time thereafter the area of operation was capable of withstanding a hydrostatic pressure of over one pound per square inch without leakage. 2. The clinically infected specimens leaked at minimum pressures. 3. To obtain perfect results a proper technic was essential. For it was seen that in a dog recently killed the intestine, when properly sutured, was capable of withstanding a pressure of nearly two pounds per square inch without leakage. 4. Imperfect technic resulted in a defensive suture line. The defects, if not too extensive, might be sealed by the coagulum which probably prevented leakage. 5. The smooth muscle of the divided and sutured intestine retained its viability and segmenting function to within five mm. of the line of suture. 6. In an infected case with gangrene around the suture line, no segmentation occurred within fifteen mm., while sixty mm. away contractions were powerful and well defined. 7. Repair in sutured intestinal wounds began at once with the coagulation of the extravasated blood, which filled in the space between the two approximated serous surfaces. The union became permanent in from seven to ten days with the replacement of the coagulum by connective tissue. 8. Repair of the mucosa was first seen after twenty-four hours beginning with a line of syncytial epithelial tissue extending from the edge of the viable mucosa over the denuded surface of the infolded cut edges of the intestinal coat. 9. The denuded surface might be covered with an immature mucosa as early as the fifteenth day (Mill), but it was usually not completely covered until twenty-three days after operation. 10. Regeneration of the mucosa was complete after two months. 11. Complete anatomical regeneration of the muscularis did not occur. A realignment of the infolded muscular fibre occurred, but it was always interrupted by a thin line of scar tissue. From the foregoing data they concluded that fluid and food might be given immediately after operation without danger of leakage into the sutured small intestine.

Prevention of Amebic Dysentery.—J. Gordon Thomson and D. Thomson (*Brit. Med. Jour.*, June 24, 1916) advise that every effort should be made to prevent the patients from becoming chronic cyst carriers, and that this is best accomplished by thorough emetine treatment. The intermittent use of small doses of emetine should be avoided and the continuous administration of one grain daily for seven to ten or more days should be practised. The results of treatment should be controlled wherever possible by examinations of the stools soon after treatment and at some time later. Cyst carriers may be rendered noninfective by the administration of emetine combined with a dose of two drams of magnesium sulphate every four hours. Usually the cysts will be cleared out after ten grains of emetine have been given in this manner. Microscopic examination of the stools is necessary to be certain of the cure. The prevention of the disease can best be accomplished by strict attention to the disinfection of the stools, by keeping flies away from them, by destroying flies, screening the houses and by covering all foods so as to make them fly proof. All fruits and vegetables usually eaten raw should be thoroughly washed and immersed for a few seconds in boiling water before being eaten.

Concerning Operations for the Craniocerebral Wounds of Modern Warfare.—Harvey Cushing (*Military Surgeon, July*, 1916) comes to the following conclusions: There is a fairly universal agreement that almost all cranial wounds produced by projectiles, even though they appear trivial, require surgical investigation, with the possible exception of certain of the tangential longitudinal sinus injuries, which according to Sargent and Holmes, have a high degree of spontaneous recoverability and which when investigated present unusual surgical risks, and of certain of the fractures of the base due to perforating wounds, owing to their inaccessibility. There is, however, a wide divergence of opinion as to when and where these operations should be performed. It is recognized that cases treated immediately at a field ambulance appear to do well for a time, but are apt to suffer from complications after their evacuation. These complications are often ascribed to the patient's transportation, whereas in greater probability they are due to the fact that these early interventions of necessity are hurriedly undertaken and imperfectly executed, and that the wound must often be evacuated at about the time when complications from sepsis are likely to occur. With the exception

of the more serious injuries with extensive hemorrhage, in which surgical measures are practically unavailing, craniocerebral wounds as a rule present no immediate urgency, for as a tissue the brain is notably tolerant of contusions and infections. Hence a delay of two or three days in forwarding this class of wounded with expedition to a suitable base is preferable to the delay of two or three days in having them recover from the effects of an incomplete procedure before transportation. We can rarely tell from the external appearance of these wounds how serious a matter the intercranial exploration will prove to be, and if the procedure is abandoned after a trifling crucial incision with a possible trepanation and the removal of a few fragments of bone and clot followed by a gauze pack, a herniation, fungus and infection will often ensue.

Avoidance of Crutches after Amputation.—Depage, at a meeting of the Société de chirurgie, Paris (*Presse médicale*, May 25, 1916), advised strongly against the giving of crutches for ambulatory purposes to patients recently subjected to leg amputation. The crutches are harmful in that they alter the static conditions of the body, immobilize the stump, and often induce muscular paresis of the arms through pressure on the brachial plexus. Instead he recommends the use of a provisional artificial limb made of plaster in which are imbedded strips of metallic netting, such a limb provided below with a wooden shaft moulding itself exactly to the stump and answering all requirements for locomotion under normal static conditions. The apparatus can be easily renewed at intervals as the stump undergoes the usual changes in size and shape, and when the ultimate, permanent condition of the stump has been attained may be replaced by a true artificial limb of one of the customary varieties.

Duration of the Immunity Produced by Antitetanic Serum.—L. Bérard and A. Lumière (*Bulletin de l'Académie de médecine*, May 30, 1916) lay stress on the necessity of administering a fresh injection of tetanus antitoxin, regardless of the possibility of serum disease, before any operative procedure is carried out in patients suffering from infected wounds, even several weeks or months after the injury. Most of the twenty cases of tetanus recently under their care could have been prevented if this precaution had been taken. A question arises as to the duration of immunity after the first preventive injection. According to the animal experiments of Roux and Vaillard, this immunity begins to wane on the fifteenth day and disappears in forty to fifty days. In man, an effectual immunity lasting twenty to thirty days after two ten c. c. injections of serum has been considered the average result. The authors now report, however, four cases in which the development of tetanus showed that protection was no longer sufficient seven or eight days after a single serum injection. Persistence of immunity cannot, therefore, be counted on for more than six days. In badly infected wounds it is consequently advisable to repeat the serum injection even if only five or six days have elapsed between the first injection and the surgical procedure to be carried out. It is shown, furthermore, that a single serum injection is insufficient to protect against tetanus. Two injections should always be given in cases with wounds presumably infected, the second from the fifth to the eight day after the first.

Vomiting in Infancy.—J. Epstein (*Medical Record*, June 24, 1916) divides causes of vomiting in infancy into four classes—improper feeding, improper food, congenital pyloric stenosis and rumination. Pyloric stenosis has three chief symptoms—persistent projectile vomiting, persistent constipation and persistent loss in weight, while the three chief physical signs are visible gastric peristalsis, palpable gastric tumor and gastric retention of food.

Operative Treatment of Osteoarthritis.—W. I. de C. Wheeler (*Lancet*, June 24, 1916) reports the case of a young woman, the victim since childhood of a marked metastatic osteoarthritis, to show the exceedingly good results which may be secured from operation in cases of this type. She was completely crippled in both lower extremities. At two sessions the new bone was chipped off the tibia of the left side and full motion was quickly regained; then a ring of bone was removed from the region of the neck of the right femur with equally good results. In both instances the operation not only restored the possibility of free motion, but also relieved the pain at once. Subsequent massage and exercise led to restoration of function in both lower extremities and there has been no recurrence of the disability since the operation in 1912.

Pediculosis pubis.—Douglass W. Montgomery (*Canadian Practitioner and Review*, June, 1916) states that the common use of blue ointment seems unwarranted both on account of its uncleanliness and because it is particularly liable to give rise to a severe dermatitis. A more satisfactory and entirely clean method of treatment consists in the application of a lotion of the following composition:

℞ Xylol, ... 50.0;
Ætheris, }
Alcoholis, } ..... āā 25.0.

M. et Sig. Rub into the affected regions with a wad of cotton.

This application kills instantly all of the adult pediculi as well as the nits, but it has the disadvantage of being quite painful for a short time after its application. Perhaps a better method, because not painful, is the application of the tricresols, for which purpose creolin is satisfactory. This may be made into a salve as follows:

℞ Creolini, ... 10.0;
Petrolati, ad ..... 100.0.

M. et fac unguentum. Sig. Apply with thorough rubbing once daily.

In addition to killing the parasite this application has the great advantage of being antipruritic and curative of any eczema which may have developed as the result of scratching. If it is desired, a five per cent. ointment of betanaphthol may be used in place of the foregoing, but there is some danger of systemic poisoning from the latter preparation. The nits may be removed from the hairs by combing with vinegar.

Miscellany from Home and Foreign Journals

Direct Traumatic Arteriovenous Aneurysm.—Soubbotitch (*Bulletin de l'Académie de médecine,* May 30, 1916) states that among forty-two cases of traumatic arteriovenous aneurysm met in the Serbian army in the last four years, and all operated in by him, twenty-four were of the direct type, artery and vein being in immediate communication. The common carotid artery was involved in three instances; the subclavian in one; the brachial, two; external iliac, three; femoral, thirteen, and popliteal, two. Often no hematoma around the affected vessels was found. Symptoms generally began only a few days and sometimes one or two weeks after the injury, the most characteristic sign being an audible thrill originating at the point of communication of the vessels and transmitted centrifugally along the artery and centripetally along the vein. At operation, especially in cases of external iliac or femoral involvement, a pronounced dilatation of the vein at and above the point of communication was noticed; likewise, a narrowing of the arterial trunk below this point. Thus, a part of the blood brought by the artery, entering the vein, is transmitted by the latter, not in a peripheral, but in a central direction, toward the heart. The centripetal transmission of the thrill along the vein and the absence of peripheral varicosities are thus accounted for in these cases of direct arteriovenous aneurysm.

Agglutination Reactions with Normal Serums.—T. R. Ritchie (*Lancet,* June 24, 1916), in order to gain a correct appreciation of the facts regarding the agglutinating powers of serum from normal persons toward the typhoid and dysentery groups of organisms, studied serums from 800 persons who, so far as could be determined, had never suffered from any of the diseases concerned and who had not been in intimate contact with such cases. In addition the reactions of others who had been exposed to the organisms of these diseases, but who had not been ill, were tested. The latter group included hospital habitués, laboratory workers, physicians, nurses, and orderlies. A simple and accurate technic was developed and used throughout the observations. The conclusions were that suspicion should be aroused: Of typhoid, when there was complete agglutination in a dilution of one to sixteen; of paratyphoid A or B, when complete agglutination occurred at a similar dilution; of dysenteric infection, when the Shiga bacillus was completely agglutinated at a dilution below one to sixty-four; and when the Flexner organism was agglutinated below one to 128. The reaction should be regarded as diagnostic of the corresponding infection, when B. typhosus or B. paratyphosus A or B, was agglutinated completely in a dilution of one to thirty-two or higher; and of the dysenteries, when the agglutination was complete at or above the dilutions stated as being the upper limits of suspicious reactions. It was found that only a small proportion of strictly normal individuals—in the restricted sense of being free from previous infection or inoculation—gave suspicious reactions to any of the organisms, and closer investigation of the suspicious cases often suggested the previous occurrence of a mild unrecognized infection by the organism in question. On the other hand the proportion of suspicious reactions found was relatively much higher among the hospital and laboratory workers and the hospital class of patients. A further point of interest was, that women showed a much higher proportion of high dilution positive reactions for all of the types of organisms than did men. This is in accord with the registrar's statistics for epidemics, which show that the proportion of men infected considerably exceeds that of women.

Etiology of Uterine Prolapse.—Gibbon Fitzgibbon (*Surgery, Gynecology and Obstetrics,* July, 1916) observes that: 1. Prolapse of the uterus and cystocele are due to damage of the pelvic fascia in the region of the lateral fornices and in front of the cervix. 2. Prolapse of the uterus must be clearly differentiated from cystocele; they may exist separately or may be combined. 3. Laceration of the perineum and levator ani muscles has no part in the production of prolapse. Laceration allows an increase of cystocele when this is the primary defect. 4. Retroversion of the uterus has no tendency to produce prolapse. 5. Prolapse of the uterus and cystocele are analogous to abdominal hernias through scars due to defective union of the fascia. 6. The cure of prolapse may be effected by reuniting the fascial diaphragm across the pelvis. 7. The fascial diaphragm may be repaired without interfering with the function of the uterus or dislocating the bladder. 8. The condition may be treated in exactly the same manner before and after the menopause. 9. Atrophy of the uterus has no influence upon its support. 10. Amputation of the cervix, other than the removal of an hypertrophied lacerated vaginal portion, is not necessary.

Cerebral Rheumatism.—J. Colombe (*Paris médical,* May 27, 1916) reports the case of a man twenty-seven years old, who, since the age of ten years, had suffered from repeated more or less severe rheumatic attacks. In the last attack, after involvement of various joints in the extremities, treated satisfactorily with salicylates, the spinal column became affected, becoming painful and rigid, at first in the lumbar region. Persistent temporal headache then followed, together with agitation, mental torpor, jerky speech, tremor of the lips and tongue, carphologia, photophobia, Kernig's sign, exaggerated knee jerks, and a positive Babinski on the left side. The heart showed enlargement and a double murmur. In spite of treatment, bilateral epileptoid oscillations appeared, with marked torpor, incontinence of urine, progressive emaciation, pupillary inequality, low delirium, albuminuria, and ultimate high fever and death. Lumbar puncture on three occasions during the course of the disease yielded a slightly turbid fluid, issuing under low pressure, with numerous polynuclear cells, a few mononuclears, and occasional lymphocytes and erythrocytes. Repeated cultures and guineapig inoculations gave

negative results. The case is recorded as one of acute meningitis developing in the course of articular rheumatism. Thus, the cases grouped under the term, cerebral rheumatism, apparently include instances of a meningeal localization of the rheumatic poison, whether this is manifest in the customary cellular reaction, as in the present case, or in a hemorrhagic process, as in cases already reported by Moutard-Martin, P. Weil, Robin, and Lyon-Caen.

Diagnosis of Dextrosuria and Pseudolevulosuria.—P. J. Cammidge (*Lancet*, June 17, 1916) finds that the presence of pseudolevulose is not uncommon and often leads to the mistaken diagnosis of glycosuria. If Benedict's solution is used and a positive reaction appears only after cooling, the presence of pseudolevulose is suggested. The presence of this substance may be determined with certainty by Seliwanow's reagent. Tests are also given for the determination of both dextrose and pseudolevulose when present together. The importance of this differentiation lies in treatment, diabetes requiring the restriction of carbohydrates, and levulosuria the restriction of protein and the use of an abundance of carbohydrates.

Condyloma acuminatum.—A. Ravogli (*Jour. A. M. A.*, July 8, 1916) reports two cases of this condition, occurring in the anal region of the male, because of relative rarity and the existence of doubt as to its relation to venereal disease. Close study of these two cases led the author to the conclusion that these papillary acanthomas were only indirectly related to venereal disease—the latter merely being the primary source of the irritation which led to the exposure of the cutaneous papillæ to excessive stimulation by irritant secretions, such as purulent material, sweat, etc. The two cases reported arose in syphilitic patients, but in neither case was the condyloma related in any direct way to the action of the syphilitic organism and neither case showed the histological picture of syphilitic inflammation. Neither case responded to antisyphilitic measures, so far as the condylomata were concerned. The proper treatment of these warty growths is their appropriate surgical removal with cauterization of the remaining base.

Intestinal Disturbances in Congenital Syphilitics.—Gaucher (*Bulletin de l'Académie de médecine*, May 23, 1916) finds that the father of "delicate" children, chronically afflicted with digestive disturbance and enteritis, is generally a former syphilitic. The intestinal disorder in these children is characterized by constipation lasting several days, with much gas formation and tympanites, followed by diarrhea with glairy, mucomembranous, occasionally bloodstained stools. Abdominal pains accompany both phases of the disturbance. The skin exhibits an earthy tint, the limbs are thin, and the abdomen is protuberant. Careful examination of such children not infrequently reveals undoubted stigmata of inherited syphilis, such as slight cranial or facial asymmetry, slight convergent strabismus, a prognathous lower jaw, and dark, fragile, and badly aligned teeth. Intestinal digestion later improves gradually, but attacks of enterocolitis recur throughout childhood and adolescence. Some of these children acquire appendicitis, of which the enterocolitis is often but a prelude. Adenoid vegetations not infrequently coexist, the reticular tissues of the appendix and pharynx having alike been affected by the syphilitic virus. Treatment in these children should consist, under pretext of applying antiphlogistic or tonic measures, in mercurial inunctions on the abdomen or injections of mercury. The preparation may be dispensed by the druggist under some name other than mercury. Astonishing and excellent therapeutic results will thus often be obtained which will confirm the suspicion of syphilis as a predisposing factor.

Proteose Intoxication.—G. H. Whipple (*Jour. A. M. A.*, July 1, 1916) states that the intoxication occurring in intestinal obstruction is due to the development and absorption of a primary proteose which may be isolated in pure form and which upon injection into animals is capable of reproducing the typical symptoms. The observations have now been extended to include peritonitis and acute pancreatitis, and in both of these conditions the same proteose has been demonstrated to be the cause of the toxic symptoms. In all of these conditions one of the most characteristic features is a marked rise in the noncoagulable nitrogen of the blood. Precisely the same condition can be produced in dogs with established nitrogen balances by the injection of small amounts of the isolated proteose. The rise in the blood nitrogen is marked and must be taken as indicating an action leading to the destruction of some of the tissue proteins. The proteose which has thus been found to be concerned in the production of the intoxication in these conditions is resistant to digestion by the ferments of the intestinal mucosa and the pancreas. An interesting feature of its action is that if an animal survives a dose of this proteose it will be found to have become tolerant to further injections of this or of other proteoses.

Skin Affections in Military Practice.—Milian (*Paris médical*, May 6, 1916) observes that tuberculous skin lesions and vesicular eczema have proved uncommon in the military hospitals, doubtless in part owing to the process of selection exercised in admitting individuals into the army. Phthiriasis has been the chief dermatological affection encountered, and has presented itself in the otherwise rare acute form, in which parasitic invasion is so extensive that almost the entire body is covered with small, edematous, almost urticaria-like papules of about the size of a pinhead. These are especially marked just below the posterior margin of the axilla—a feature distinguishing phthiriasis from scabies, in which the anterior aspect of the axilla is chiefly involved. The immediate care given these cases has prevented their passage into the chronic state, excoriations and melanoderma being therefore infrequent; ecthyma of the lower extremities, however, has been an almost universal complication of phthiriasis in soldiers. Scabies has been relatively uncommon, and when present, has almost always been preceded by coitus, the mode of life in active warfare being unfavorable to transmission of the disease. Impetigo, ecthyma, and trichophy-

tosis have been frequent, the last named occurring sometimes in epidemics. "Trench foot" is a newly observed affection, now thought to be of microbic origin. Prophylaxis consists in measures to avoid prolonged wetting of the feet and curative treatment in hot foot baths two or three times daily, special movements of the feet, and light moist dressings with hydrogen peroxide solution diluted to one in ten, or wrapping the feet in cotton at night.

Importance of Method in Isolating Organisms of the Typhoid Group.—C. H. Browning and L. H. D. Thornton (*Brit. Med. Jour.*, May 13, 1916) call attention to the importance of discovering the largest possible proportion of actual carriers of the typhoid group of organisms among suspects, and several methods for the isolation of these organisms from the stools are discussed. The use of brilliant green gives the most satisfactory results, but several tubes, containing different concentrations of the dye, should be inoculated instead of trusting to the use of a single tube containing the supposed optimum concentration. The further addition of varying amounts of telluric acid to some of the tubes containing the dye adds materially to the certainty of isolation in doubtful cases.

Parenchymatous Disease of the Liver as a Cause of Rise in Portal Blood Pressure.—C. F. Hoover (*Jour. A. M. A.*, July 1, 1916) has encountered difficulty in determining the cause of the increase in portal blood pressure and its secondary manifestation of ascites in cirrhosis of the liver. This is particularly true since post mortem there does not seem to be any demonstrable interference with the flow through the liver vessels. From close observation of a specially favorable case Hoover is able to bring forth much evidence to support the belief that one of the causes of increased portal blood pressure in such cases may be the occurrence of a parenchymatous inflammation of the liver. Such inflammation is usually subacute and often transitory, and this is generally true in cirrhosis with ascites which alternates with periods of freedom from swelling. In Hoover's patient the occurrence and subsequent subsidence of parenchymatous inflammation and edema of the liver could be discovered clinically with little reason to doubt the accuracy of the observations. The proof of the elevation of the portal blood pressure coincident with the attack of enlargement of the liver and tenderness over it was derived from the study of the circulation in the enlarged superficial abdominal veins and the alterations in a murmur present, coincident with the changes in the state of the liver.

Dermatitis cupoliformis.—Aldo Castellani has noted this affection (*Journal of Tropical Medicine and Hygiene*, February 15, 1916) for several years in Ceylon; he also terms it "tropical ecthyma." It begins with several superficial, dusky red, slightly itching spots, generally follicular and perifolliicular, and as a rule situated on the feet and legs. Some of these spots enlarge, become raised and hard, without vesication or pustulation, and often somewhat cupped, reaching the size of a pea to that of a small cherry. After a time an ulcer forms with reddish fundus and often undermined edges. Spontaneous cure seldom occurs in less than ten to twelve months. It affects mostly young European men. Castellani has isolated from the lesions a special organism which he has termed Streptococcus tropicalis, with which he has reproduced the disease by inoculation. The nodules are most often mistaken for oriental sore, but the absence of the Leishmania is distinctive. In true ecthyma the initial lesions are pustular. The condition is also to be differentiated from pyosis tropica, purulent folliculitis, Barkoo rot, ulcus infantum, blastomycosis, syphilitic ulcers, and veldt sore. Treatment with bichloride or peroxide lotions, followed by balsam of Peru ointment, is of some slight use, but acts very slowly. By far the best treatment is the use of an autogenous vaccine, which may cure a previously obstinate case in two or three weeks.

Relation of Ductless Glands to Blood Pressure.—J. G. Sweet (*International Abstract of Surgery, Gynecology and Obstetrics*, June, 1916) concludes that in hypoplastic conditions, such as status lymphaticus, and after chronic infective conditions and acute intoxications commonly met in surgery, the chromaffine system is not normally productive. If we agree with Cannon that this product is a reserve for times of stress, we find a basis in theory in addition to the teachings of common humanity, for the avoidance of all preoperative influences which tend to cause fear or excitement; if we agree that ether creates an abnormal demand for this chromaffine product, we have a basis in theory for the use of gas oxygen; in any case in which a hypofunction of the chromaffine system is suspected, or in which an extraordinary demand for this substance may be expected, the use of small amounts of adrenaline continuously administered in saline solution during the operation is indicated.

Influence of Tonsil and Adenoid Abnormalities upon Health and Oral Development.—W. F. Clevenger (*Lancet-Clinic*, June 10, 1916) states that perhaps more real harm is done by the apparently innocent, small, imbedded, diseased tonsil than by the conspicuous type, the latter presenting an open surface from which drainage is far more likely than it is from the organ submerged and covered by the pillars. Enlarged crypts, acting as receptacles for bacteria, greatly favor absorption of toxic material and usually may be considered the source of acute or chronic retrotonsillar abscesses. The tendency toward chronic posttonsillar infections and resulting more or less chronic systemic disturbances is much greater in adults than in the young. Thyroid hypertrophy is often due to infection of tonsillar tissue, and childhood torticollis, even of months' duration, may be similarly caused. In addition to joint, heart, and mastoid affections, nephritis may in some instances be traced to throat infection. Chronic abscess cavities between the tonsillar capsule and constrictor muscle are most potent factors in the often encountered and wrongly diagnosed low grade septic states. Even after the removal of tonsils and adenoids, imperfect breathing due to structural deformity of the upper maxilla often results in permanent nasal deformities in adult life. Many children after the tonsil and adenoid operation therefore require reference to an orthodontist, for correction of the maxillary deformity.

Proceedings of National and Local Societies

NEW YORK ACADEMY OF MEDICINE.

Special Meeting to Discuss the Subject of Infantile Paralysis, July 13, 1916.

The President, Dr. WALTER B. JAMES, in the Chair.

President's Address.—Dr. WALTER B. JAMES, president of the New York Academy of Medicine, introduced the speakers in turn with appropriate explanation of their particular authority to speak on the subject they chose. At the close of the meeting he invited all present who were interested in asking questions of those recognized as authorities on the subject of the evening, to convene at the Academy, where this could be done while taking light refreshments. He congratulated Doctor Emerson on the work of the department of health, and the efficacious manner in which the epidemic had been handled, and expressed the gratification of all that in spite of the great heat of the last few days, the daily number of cases reported had diminished, indicating that the epidemic was probably now under control.

What We Know About the Transmission of the Disease.—An abstract of this paper, by Dr. SIMON FLEXNER, appears in this issue of the NEW YORK MEDICAL JOURNAL, page 168.

The Clinical Types of the Disease.—Dr. HENRY KOPLIK said that poliomyelitis was primarily an epidemic disease, and as a sporadic condition had attracted very little notice. All the epidemics which had thus far been recorded resembled each other very closely. An attempt to connect this disease with the occurrence of cases of cerebrospinal meningitis had developed into a belief that poliomyelitis was an entity, clinically occurring in epidemics in the late spring to late autumn, and following the regular sporadic occurrence of the disease in limited numbers in the months following the winter and reaching into the late spring up to the time of the epidemic outbreaks. Epidemics of this disease had been known to skip a year and always to crop up in the place of its original occurrence, which should give the thoughtful a hint as to its cause and epidemiology. In all the epidemics thus far recorded, the symptomatology and clinical types had been much the same.

Though most of the scientific knowledge of the clinical types of poliomyelitis was borrowed from Swedish and Norwegian observers, Medin and Wickman, the first inkling of the epidemic nature of the disease was voiced by Colmer, an American physician, who in 1841 observed some form of paralysis in a child and obtained the history that in the locality in which the patient lived several similar cases had occurred, most of them ending in recovery. Following him, Caverly, in 1894, described an epidemic in Vermont; Taylor and Chapin later on observed the epidemic nature of the disease. Aside from these observers, much of the clinical knowledge at present was due to Medin, who described the clinical types of acute epidemic poliomyelitis in 1884 before the International Congress, much to the astonishment of most pediatrists, who still retained the simple picture as given in older textbooks, of poliomyelitis anterior as a simple, infantile paralysis. In all, forty-two epidemics had been observed in America and on the Continent, and this alone would establish the tendency of poliomyelitis to occur in epidemic form at certain seasons and remain sporadic until the time arrived for a new outbreak.

The disease selected the young as its victims. Out of 886 cases in the epidemic of 1907, 571 were in children below three years of age, 771 below five years, and three were under six months of age. In the present epidemic, the youngest patient the author had seen was a baby four and a half months old and absolutely breast fed. The most susceptible period was from one to three years of age. There were four principal types which could be clinically fully described and proved by laboratory methods: the abortive, the bulbospinal, the cerebral and meningeal, and the bulbopontine types. Wickman also described a neuritic type. These types could all be understood when poliomyelitis was regarded from the standpoint of an acute, infectious disease, involving certain parts of the general nervous structures, causing certain definitely marked pictures and stopping there, or going on to involve at one stroke the whole cerebrospinal axis and in this way causing a *débâcle* of the whole substratum of the nervous economy.

It was through the abortive type of the disease that these cases were spread to others. This type did not go on to paralysis, recovered, and did not leave the host injured as to the muscular motor apparatus. This type could be recognized so as to leave no doubt as to its distinct identity. A child of five years of age was attacked with a headache, slight malaise, and vomiting lasting five days, intense pain in both lower extremities radiating to the soles of the feet and worse at night, slight pain in the nape of the neck; lassitude, cerebellar gait on walking, increased reflexes in the lower extremities, rectal temperature rarely above 100.5° F. In ten days the pains disappeared, the child was well, and wanted to go out and play. The abortive cases presented prodromata, such as headache, weakness, diminished reflexes, and pain in the nape of the neck, with or without vomiting and fever, and still did not present paralysis, and recovered.

The spinal, or bulbospinal type was the most common and gave the disease its name. The patient had an attack of vomiting and slight fever and within twenty-four hours the mother observed the child could not move one or the other extremity. These forms might have no fever, but it was possible in giving the history the mother might have overlooked the symptoms of fever, malaise, and such indisposition as peevishness, which might have preceded by a few days the paralysis. In other cases, the paralysis appeared gradually. Pain might continue to be severe, especially when the extremities were moved. The paralysis might spread and involve not only the remaining lower extremity, but the up-

per extremities, the muscles of the back and respiratory muscles of the thorax, and possibly the muscles of the abdomen. As a rule, in the purely spinal cases, the paralysis appeared and did not spread. In others, it might spread from the extremities and involve the whole trunk, even causing bulbar paralysis of the respiratory centres. But after the tenth day, paralysis was not apt to spread to the bulbar medulla, though cases had been known to be fatal after the fifteenth day.

Both the meningitic and cerebral types should be combined because of the cerebral symptoms which gave rise to a picture closely simulating meningitis. The meningitic form of poliomyelitis ran its course with cerebral symptoms. A child of three years was taken with vomiting for forty-eight hours, followed by rigidity of the neck with pain on flexion of the head, Brudzinski sign and reflex, Kernig, sopor, and Macewen's sign which might be slightly marked; also diminished knee reflexes. Some patients might improve after a day or two, the fever might abate, and they might even be about and then have a recrudescence of fever, sopor, rigidity, delirium, irritability, extreme hyperesthesia, and pain in the nape of the neck. In some cases the only palsy might be ocular; in others a slight facial palsy might be present combined with weakness in one or other extremities. After a week, the patient became brighter. There was still, however, marked ataxia and Romberg's symptom. As convalescence was established, the ataxia was the last symptom to disappear. The hydrocephalus and abnormal mental state might remain for some time after the temperature was normal. On recovery, there was a slight strabismus, ataxia, optic neuritis. In one group of cases the writer had seen unilateral ophthalmoplegia with hemorrhages into the retina. In lumbar puncture lay the differentiation in the form of poliomyelitis from cerebrospinal meningitis.

The bulbar or pontine type of the disease deserved notice as a distinct form. An infant, breast fed, thirteen months of age, was attacked with fever and vomiting. The fever continued into the afternoon of the following day, when the mother noticed a flatness of the right side of the face. The temperature continued at 102.4° F., the infant was bright, laughed and played in the crib, but there was a tired look about the face and eyes. The knee reflexes were increased, otherwise there was no paralysis that could be demonstrated. In another case, ten days before the patient, aged twenty-one months, was seen, he was taken with high fever and vomiting, and there were some green movements. The fever continued, in a less degree, to the ninth day, when the mother noticed that the right side of the face was flat, there were tremulous movements of the head and arms, and the patient was restless. There was constant jactitation of the head and insomnia; rigidity of the neck, but no palsies of the extremities; on the contrary, the patient exhibited great strength in both the upper and the lower. In other cases, the outcome was not so favorable; there was an involvement of the nuclei which controlled deglutition and respiration. In these cases the patient might be lost by paralysis of the respiratory centres. The neuritic type included cases in which pains in the extremities became a leading feature of the clinical picture. In some of these cases paralysis developed; in others it did not. They were referred to in this paper under the head of abortive cases.

The symptoms given justified a lumbar puncture in order to establish the character of the fluid which in poliomyelitis showed a lymphocytic cytology, and an increase of globulin. The examination of the blood was very uncertain.

As to prognosis, the low mortality of ten per cent. applied to children below eleven years of age and twenty-seven per cent. among older children and adults. Twenty per cent. of all cases ended in complete recovery, and the younger the child, the better the prognosis.

Abortive and Nonparalytic Cases; Their Importance and Their Recognition.—Dr. George Draper, of the Presbyterian Hospital, said that if the cases of poliomyelitis progressing to paralysis were typical of the disease, the term, abortive, was incorrect and should be replaced by atypical; but as a matter of fact, the cases which fortunately escaped paralysis were just as truly cases of the disease as those which did not and were in reality more dangerous to the community.

At this time, there was no way of knowing accurately the proportion of those having the disease who were nonparalytic and those who were paralytic. In one of Wickman's groups, at autopsy, out of four cases, three were not paralyzed. In another group of four, two were not paralyzed. In Muller's group of three cases, one was paralyzed, in one the reflexes were lost, and the third was negative. In general, all abortive cases fell into groups; those with gastrointestinal symptoms, those with respiratory symptoms, those with febrile symptoms, and those with symptoms of meningismus. There were also cases with possibly transient paresis. The paralysis cases might have the prodromata of any of the first four groups mentioned. The intensity of the symptoms was no guide to prognosis.

The cases of poliomyelitis with gastrointestinal disturbances might easily, from the symptoms, be diagnosed as other than the true condition. The respiratory cases complained of influenzalike aches and pains. In the febrile cases, careful watch would disclose transient weakness, local muscle tenderness and the spinal flexion sign. On the slightest suspicion, spinal puncture should be done at once. This should be done also in the cases of meningismus, when a positive differential diagnosis from tuberculosis or epidemic meningitis could be made.

No doubt many abortive cases existed. It was absolutely necessary that they be recognized, for a double advantage would result; as moving sources of contagion they would be controlled, and patients who were otherwise destined to be paralyzed would be recognized to be in danger in the preparalytic stage and, when a specific remedy was finally discovered, probably cured without subsequent crippling.

Dr. Louis C. Ager, visiting physician to the Kingston Avenue Hospital, Brooklyn, said the city might well be proud of the way it had handled this epidemic and of the adequate hospitalization

of such a large number of cases. Many valuable data on the subject of poliomyelitis were now being carefully gathered, and later, when the heavy clinical work had lessened, would probably prove of infinite value, as the only other large epidemic of this disease, in 1907, had not been recognized until it was over. In regard to the hospitalization of the cases, too much could not be said in praise of the way the emergency had been met. This would be better appreciated when it was recalled that from June 20th until July 12th the Kingston Avenue Hospital alone cared for 320 cases. The resident staff were thus brought suddenly face to face with a large number of serious problems, and an immense amount of work to be accomplished. A specific incident would illustrate this more fully. On July 3d there were eighty-nine cases admitted to the hospital. During that day the ambulance surgeons had only three hours sleep and no meals.

That hospital care was advantageous was apparent in the change observed in many of these little children as a result of the facilities offered for making them comfortable. Put in cool, clean, comfortable beds, with fresh air blowing in from windows on each side of the ward, it was wonderful to see the almost immediate effect. There had been some difference of opinion as to the infectivity of the disease, and this had not yet been decided. Doctor Draper had spoken of the large number of abortive cases, and in this class there was more proof of the infectivity of poliomyelitis than there was before the epidemic of 1907. The speaker reported the two following examples: On July 2nd, a child was taken sick with convulsions, vomiting, and fever and recovered; on July 3d, another child in the same family was stricken with the acute fulminating type of the disease and died within forty-eight hours; on July 4th, an older member of the family manifested the disease. A second group of cases was as follows: On June 28th, a child became ill with an abortive type; on June 30th, a second child came down with the fulminating type and death followed; on July 5th, a third case occurred in this same family which in this instance was followed by paralysis. There must be a large number of abortive cases that were not recognized. In the Kingston Avenue Hospital there were at least eight series of cases where there had been two or more victims in the same family. A great many more instances of this kind would have been found if there had been more complete statistics in 1907. About the only statistics on this point were those published by Wickman and Medin in Europe.

It had been remarked by some observers that blond rather than brunette children had been the chief victims of poliomyelitis; on this point the speaker did not care to give an opinion, but he could state positively that there must be few cases among negroes as among the 350 cases in the Kingston Avenue Hospital there had been no colored children. Some investigators had tried to find a relationship in the incidence of the disease to light complexioned people, but such relationship had not been traced. The incidence of the disease was likewise practically the same in all nationalities.

In reference to the affection of the liver and spleen in this disease, it could be stated that in this respect, so far as the clinical signs were concerned, there was no enlargement of these organs, except in some fulminating cases. This was a systemic affection and, like tuberculosis in small infants, involved the entire system. Only two instances of an enlarged liver were found in sixty-seven cases.

The age incidence in the present epidemic was practically the same as in the epidemic of 1907. It was peculiar that in epidemics in this country the age incidence was lower than in those on the other side. Of eighty-seven cases, forty-six occurred between the ages of two and five years; twenty-two between the ages of one and two years; eight between the ages of six and twelve, and three between one and six months. There were two adult cases in this group; one in a woman twenty-eight years of age and one in a pregnant woman of twenty-one years.

As to the types of the disease, in the clinical work three had been distinguished: the encephalitic, the myelitic, and the meningitic. Perhaps this classification was not scientific, but it had been found valuable for bedside work. It was found, as usual, that the lower extremities were most frequently paralyzed; in a group of sixty-four cases examined, the lower extremities were involved in thirty-nine, in seven instances the upper extremities, in five there was facial paralysis, and in thirteen cases the only definite symptom was paralysis of the muscles of the back. There were two typical ataxic cases.

The fulminating fatal cases gave the most pronounced symptoms. There was one peculiar and unusual case of a boy of eleven years, who was well nourished and well developed. He was brought in when his only symptom was labored breathing. There was a slight blur in his speech and he could not swallow milk on account of pharyngeal paralysis. His diaphragm was completely paralyzed, and the labored breathing was accomplished by the thoracic muscles alone. He could stand in bed and use his arms and hands, and his back showed no evidence of paralysis. He gradually became weaker and died five hours after entering the hospital. Another case of the fulminating type showed a general paralysis; practically all the skeletal muscles were affected, and there was marked respiratory paralysis. In both of these cases the heart was not affected and continued to beat for some time after respiration had ceased. Immediately after death artificial respiration and oxygenation were tried and kept up for some time. In some instances, artificial respiration had succeeded in bringing back the color after death had apparently set in, and it was still hoped that in some cases something might be accomplished by this method. The apparatus which Doctor Meltzer used at the Rockefeller Institute was employed.

In regard to the meningitic type, there was in the hospital a boy who was wildly delirious, had complete paralysis of one leg and one arm, and was totally blind. There was an alteration in his condition from deep meningeal coma to active maniacal delirium. He died in two days. An interesting thing that occurred in this epidemic might be noted here. One of the hospital interns on responding to croup

calls on six different occasions found the patients had respiratory paralysis and poliomyelitis.

As to prognosis, it was sometimes extraordinary to see the rapid improvement in cases of this kind. The speaker had seen small bottle fed babies who were unable to take their milk at first, but in a short time were able to hold the bottle and feed themselves. There was often improvement in a few days, in the hospital, and this had strengthened the conviction that this was the best place for such cases unless the hospital conditions could be reproduced in the home.

Laboratory Aids in the Diagnosis.—This paper, by Dr. Josephine B. Neal, of the Department of Health Laboratory, appears on page 167 of this issue of the Journal.

The Importance of the Present Epidemic.—Dr. Haven Emerson illustrated his remarks with charts showing tabulated records of 1,557 cases and 311 deaths in the present epidemic, but admitted that the records were not accurate, as thus far they only showed the date on which the cases had been reported instead of following the usual plan of giving the date of the onset of the disease. For instance, in May only five cases were reported, while in July fifteen cases were reported that had had their onset in May, and obviously there was no means of knowing how many abortive cases had existed. On June 20th, the rapidly rising incidence of the disease began, until the highest point was reached on July 11th. Since that time, in spite of the great heat, there had been a recession which it was hoped would prove permanent.

At the onset of the outbreak the health department could choose between alternative courses. One was secrecy and the possible control of cases without publicity. The other was publicity and hospitalization, which seemed to offer a better prospect of real control of the disease; this plan was followed. As a result there had been undue fright on the part of the public, which seemed unwarranted when it was considered that a study of the death rates for the city as a whole, of diphtheria, scarlet fever, measles, whooping cough, and diarrhea during the last six years, and for the first six months of this year, showed that in comparison the deaths from poliomyelitis had been few. During the first six months of 1916, there were 884 deaths from diarrheal diseases and only fifty-seven from poliomyelitis. The community looked with complacency on the former, while it was panic-stricken over the latter.

This was probably the first epidemic of poliomyelitis in this city in which the disease had been made reportable and also the first in which there had been an effort at complete hospitalization. It was acknowledged that the present method of trying to control the disease was frankly an experiment. Reporting cases was new, placarding was new, and hospitalization was new. In 1907, it was not until November that the epidemic, then drawing to a close, was studied. At that time vital statistics were not as complete as now and so, while that epidemic was in progress, no study was made of it. In that epidemic there were probably 2,500 cases; there were 700 cases accurately studied by the sections in pediatrics and neurology of the New York Academy of Medicine in November, 1907. The mortality was twenty-seven per cent. During the present epidemic about 2,600 cases had been reported, but only about 1,600 of these had proved to be true cases. It was estimated that the total death rate in the epidemic of 1907 was five per cent.; during the present epidemic it had been 18.7 per cent.

The most important factors in dealing with the disease were early diagnosis and putting all cases under early orthopedic and neurological observation which might save the individual and the public from the future burden that permanent crippling implied. The early recognition of the condition was the most important factor in preventing the spread of the virus among the healthy.

During the time of this epidemic, the first opportunity had been taken to make use of the concerted action of the hospitals. This would no doubt result for cooperation in the future and would favor scientific advance in the study of the disease. It would be of advantage to have a staff suited to meet the requirements of these patients, including a laboratory diagnostician, a neurologist, an orthopedist, and a pediatrist. It seemed advisable to urge hospitals likely to have these cases to have a staff of this type for dealing with an epidemic. Social service organizations could also be made use of to a greater extent than in other conditions. There was need of concentrated follow up work in the homes of all patients, which would be a great need for years after they had left the hospital.

Splendid cooperation had been shown by the private hospitals of this city, and adequate provision had been made in the City, Metropolitan, Bellevue, Nose and Throat, Babies', Lebanon, Presbyterian, Willard Parker, St. Francis, German, St. Vincent's, Orthopedic, Mt. Sinai, Ruptured and Crippled, Neurological, and Nursery and Child Hospitals, in Manhattan; the Greenpoint, Kings County, Kingston Avenue for Contagious Diseases, Long Island, Methodist Episcopal, St. Mary's, Norwegian, Lutheran, and Samaritan Hospitals in Brooklyn, St. Vincent's Hospital in West New Brighton, and St. John's Hospital in Queens. Quarantine and the services at Ellis Island had also been placed at the disposal of the health department in case it should be required. This cooperation was a notable contribution to the city's benefit and would probably result in some permanent plan that might be put to service on such occasions in the future.

The necessity for accurate knowledge of the whereabouts of every case in the city was illustrated by the following incident. In the routine course of inspection a limping boy met the health officers and led them upstairs in a house where another small boy, also limping, was found. The baby, which was sick, had been sent outdoors in its carriage. The mother had called in no physician, though all three children were in the acute stage of infantile paralysis. She explained that she did not think they were very ill because they were active in moving about.

The speaker could not close his address without paying a tribute to the degree to which men of the

medical profession would sacrifice themselves to the public health. Many instances had arisen where physicians had for the time being lost their entire practice because they had been taking care of cases of infantile paralysis and their other patients had been afraid to come to them. Other physicians would no doubt see that these men did not suffer because of their willingness to sacrifice themselves for the welfare of those having need of their services, and it was hoped that wherever this attitude of fear of patients toward their physicians was met, it would be discouraged.

In closing, Doctor Emerson appealed for early diagnosis and a willingness to report cases on the part of the medical profession, for no health department, however efficient, could otherwise control an epidemic and secure proper police enforcement of its regulations.

Dr. Walter B. James recognized a doctor from one of the infected districts, who asked if some one present could give in detail the proper modern treatment for poliomyelitis.

Dr. Henry Koplik replied that, as the cause of the disease was still under investigation, it was not yet possible to speak of a specific treatment which at this time, instead, could only be systemic and symptomatic. The patient should be isolated and above all should be kept absolutely quiet. Any one in attendance on a patient should wear a gown and protection for the mouth and nose, and, on leaving the patient, should carefuly clean his hands and face. A German physician in Munich had recommended that the patient be placed in a Bradford frame to insure absolute rest. He should have plenty of fresh air and an easily assimilable diet. The bowels should be attended to. Medication was confined to those drugs having an effect on the general nervous system. Lumbar puncture had three advantages; in the first place, the mere mechanical removal of a certain amount of fluid which might be toxic might be of benefit; in the second place, the examination of the fluid itself helped to establish a diagnosis; and in the third place, it relieved pressure. In paralytic cases, a cast might be applied to prevent contracture. If the contracture persisted after removal of the cast, the patient should be referred to an orthopedist. Anodynes relieved symptoms referable to the nervous system, but opium should not be administered unless absolutely necessary. Intramuscular injections of strychnine could be given as soon as the pain and fever had ceased. One fortieth of a grain daily might be given over a period of thirty days, selecting different groups of muscles for the injections. Warm baths sometimes proved a great blessing, except in the neuritic cases, if given without moving the patient too much. Massage in some instances relieved pain. In some cases iodide of potassium seemed to have an anodyne effect. In no case should operations for adenoids or tonsils be performed.

Dr. William H. Park said that as the hour was so late his remarks would be very brief. If there was time, he would emphasize in detail all that Doctor Flexner had said, as in his opinion this review of the situation had been both valuable and interesting. It looked as if, with the efforts of such men as Flexner and Noguchi, the subject of infantile paralysis would shortly be clearly understood by all, and a specific cure discovered. He wished to draw attention to one point as so many of the speakers had done, and that was to the abortive cases; in every instance where it was possible to follow the infection from its source, it had been observed that the sixth person in line of infection had been the one to suffer most. The carrier spread it abroad to unknown places and in cases where there was the least suspicion, there should be isolation. The infection might be thrown out by dust; there were no known carriers, though it was known that the sick person and carriers threw out the contagion. If insects were found to be carriers, it would probably be in a subordinate way. It was difficult to believe that any given carrier or doubtful case was infectious through bacteria, as in cerebral meningitis. But if a diagnosis could be made through a culture, they could not act differently in handling the epidemic. It was of value to know that a case, whether doubtful or well developed, was the greatest source of danger to others, and that the carrier went out through the family or visitors to the bedridden, so culture or serum diagnosis was not necessary for the safety of others. If every carrier were labeled, it would have been impossible to do more in checking the epidemic than the health department was doing now. It was to be hoped that, basing the work on what had been done, it would soon be possible to announce the discovery of a specific vaccine.

Dr. Leon Louri, of Brooklyn, said that in half the cases he had seen there were no symptoms of paralysis. In a few, he had noticed a very interesting occurrence. They were taken ill with slight sore throat, slight febrile manifestations and malaise, and were treated by the usual iron mixture. In twenty-four hours the temperature was normal and the child went about as usual. On the third day, unmistakable symptoms of poliomyelitis developed with definite paralysis. If the disease could be recognized on the first day and the child placed in bed and kept quiet so that the nervous system would not be traumatized, the virus would not develop to the extent it did later. Early treatment was most important applied in abortive cases. A healthy person who had no disease in his family, might travel through an infected district and carry thence with him the virus of the disease and implant it elsewhere. The duty of every one was to call in medical men early to diagnose any case where there was the least suspicion of the presence of the virus, and not take lightly those symptoms which represented the so called types of poliomyelitis.

Dr. Samuel J. Meltzer, of the Rockefeller Institute, had decided to confine his remarks to one essential phase touched on by only one of the speakers of the evening, and that was the treatment of the disease. The discouraging fact was present that at this time there was practically no specific treatment for poliomyelitis, but he desired to bring forward three promising therapeutic measures based essentially on his personal work: Any inflammatory focus was surrounded at the periphery by zones of hyperemia, exudation, and edema. Thirteen years

ago, in experimenting upon rabbits' ears, he found that an injection of adrenaline reduced the entire inflammatory swelling to a very small focus in the centre. The peripheral zones of edema and active hyperemia disappeared completely for some time. Several years ago, he and Doctor Auer found that an intraspinal injection of adrenaline into monkeys produced a lasting effect upon the blood pressure, longer than by any other method of administration; more than one hour might pass before the blood pressure returned to normal.

On the basis of these observations and on the further plausible assumption that the early stages of the paralytic effects in poliomyelitis were not caused by the chief inflammatory focus, but by the peripheral zones of active hyperemia, exudation, and edema, the speaker induced Doctor Clark, then working under Doctor Flexner at the Rockefeller Institute, to make the following experiments: Monkeys dying from experimental poliomyelitis received intraspinal injections of adrenaline. The beneficial effect was most striking. Animals which were paralyzed and moribund at the time of the injection, were seen several hours later eating bananas which they held themselves; the paralytic conditions were strikingly improved, and the life of the animals in some cases was prolonged for several days. The animals finally died; but in this series of Doctor Clark's experiments, all animals received surely fatal doses of the virus.

If the exudation and edema could be removed for some time, the life of a few, or of many children might be saved, that is, if in these cases it happened that the ascending progress of the actual inflammation became fixed. On the basis of these facts and considerations, the speaker recommended the intraspinal injection of adrenaline in every case of infantile paralysis, the injections to be repeated in from four to six hours. The procedure might save life and, in surviving cases, it might reduce the extent of the final lesion. There was no danger in this procedure. Monkeys stood well as large a dose as two c. c. in a single injection. However, in human infantile paralysis the injections should be begun with a dose of 0.5 c. c. of adrenaline until more was learned about the effects.

He wished to make two other suggestions in regard to treatment. One was the administration of artificial respiration by means of the Rockefeller apparatus for pharyngeal insufflation, as soon as the patient showed a degree of unconsciousness and respiratory insufficiency. This was an easy and trustworthy procedure. The second suggestion was to administer oxygen under pressure in a respiratory rhythm by an apparatus which the speaker had recently devised and used on human beings in several instances. It rapidly abolished cyanosis and might save life. It might even act specifically on the virus of poliomyelitis. It was impossible at this time to describe either of these apparatus or the mode of application or the results of experiments, but this would gladly be demonstrated at the institute if a number of physicians would signify their desire in this direction and arrange for a definite appointment.

Letters to the Editors.

QUININE IN POLIOMYELITIS.

New York, *July 15, 1916.*

To the Editors:

In the course of twenty-eight years of active practice, I have been using quinine in small doses for prophylactic purposes in many infectious diseases, with most gratifying results. I have used quinine in typhoid, diphtheria, scarlatina, etc., epidemics and sporadic cases, and have never seen a patient contract any of the foregoing diseases while taking small doses of quinine, notwithstanding direct contact with such patients. I have also been using quinine in almost unavoidable puerperal sepsis, and have never seen the expected sepsis take place. I have therefore come to regard quinine as decidedly inimical to microbic life, either by possessing direct germicidal powers, or by stimulating phagocytosis, or both. Hence, I feel quite confident that in the present epidemic of poliomyelitis, which is of undoubted microbic origin, the administration of small doses of quinine to children, no matter how immediately or remotely exposed to the infection, would be found of great service in checking its spread. As is well known, this remedy in small doses is absolutely harmless (except for some very rare idiosyncrasies), simple, and inexpensive.

Although my theory is lacking in scientific proof, and may not be verified by laboratory experiments, yet from a long, practical experience, and close observation, I am compelled to adhere to it, and I may add that there is a vast difference between laboratory inoculations and ordinary natural infection or communicability, and while a certain prophylactic may not resist inoculation with millions of microbes, it may successfully fight off a few invaders in the natural process of infection.

I would also strongly suggest the application of the same treatment to poliomyelitic patients, but with considerably larger doses of the quinine, combined with appropriate doses of phenacetin and caffeine citrate.

FOR PROPHYLACTIC PURPOSES.

For children of from six months to one year, one quarter to one half grain, three times a day.

For children from one year to three years, three quarters to one grain, three times a day.

From three years to fifteen years, one grain to one and one half grain, three times a day.

In order to disguise the bitter taste of the drug, I usually combine it with licorice powder or syrup of yerba santa. The following prescriptions are examples:

FOR A BABY OF ONE YEAR.

℞ Quininæ sulphatis, ...gr. xv;
Syrupi yerba santa, ...℥ij;
Syrupi tolutani, }
Aquæ, ... } .....āā, p. æ. ad. ℥iv.

M. Sig. One teaspoonful, three times a day.

FOR A CHILD ABOUT THREE YEARS OLD.

℞ Quininæ sulphatis, ...gr. xxx;
Pulveris glycyrrhizæ, ...℥j;
Sacchari albi, ...℥ij.

M. Fiant pulveres No. 30. Sig. One powder three times a day in water.

B. Scheinkman, M. D.

AMMONIUM SALICYLATE IN POLIOMYELITIS.

New York, *July 15, 1916.*

To the Editors:

As a postscript to my special article on anterior poliomyelitis, published in your issue for July 15th, page 128, I would advise that whenever a child has been exposed to the disease, or even as a general preventive, a dose of ammonium salicylate be given three or four times in the twenty-four hours for several days. It could do no harm and I am hopeful that it might accomplish a great deal of good. To my mind the present epidemic has certain marked features which connect it with epidemic grippe. Last winter I had remarkable success in the latter disease from ammonium salicylate combined with caffeine. The liquor alkalinus antisepticus, well diluted, should be used freely as a throat spray. I believe that this combined

treatment may be at least most welcome to alarmed mothers, to whom little has been offered so far in this epidemic except vague generalities.

It does not seem to me that injections of adrenaline, as advocated by Doctor Meltzer, have any advantages over the use of ergotin hypodermically, as advocated many years ago by Althaus. Counterirritation to the region of the spine, by a liniment, such as equal parts of soap liniment and spirit of turpentine, is indicated. Also, insistence "during the early days of the disease, upon a prone position, varied occasionally by laying the patient on his side. The dorsal position, which favors congestion of the vessels within the spinal canal, should, if possible, be avoided." This citation is taken in substance from *Disease in Children*, by Eustace Smith (3d ed., 1886, p. 378). We are apt to forget things of long ago and take up others which are really not so valuable. I would not burden you again so soon, but somehow I feel I may be useful.

BEVERLEY ROBINSON, M. D.

A SUGGESTION IN THE TREATMENT OF ANTERIOR POLIOMYELITIS.

BETHLEHEM, PA., *July 17, 1916.*

To the Editors:

During the slight epidemic of infantile paralysis, in 1911, I was called upon to treat several cases. Medical literature gave nothing definite, so I thought no harm could be done by trying something unusual. Considering the possible pathology, I concluded that something which decreased the primary congestion of the cord would aid somewhat in preventing further destructive changes.

Upon this theory and the possibility that the parathyroids were upset, as is sometimes the case in infantile gastrointestinal trouble, which is often one of the early symptoms of infantile paralysis, I gave one of the calcium salts, chosen for no other reason than that it was easier to administer to young children, i. e., calcium chloride in the elixir. The action of calcium chloride is different from adrenaline chloride in that it produces an increase in fibrin, thereby increasing the coagulability of the blood. It is more lasting in action than adrenaline, which produces only a local anemia of the part of short duration, followed by a secondary increased congestion. It has no action upon the parathyroids and may be dangerous by increasing blood pressure and overtaxing a diseased heart.

I may say that all my cases made a complete recovery. I insisted upon absolute rest, the child to remain in bed and not to be moved for at least three days. This I give for the sole purpose of asking others to try this treatment, and trust that it may be of some benefit.

CARL F. WELDEN, M. D.

Book Reviews

[*We publish full lists of books received, but we acknowledge no obligation to review them all. Nevertheless, so far as space permits, we review those in which we think our readers are likely to be interested.*]

The Aftertreatment of Operations. A Manual for Practitioners and House Surgeons. By P. LOCKHART-MUMMERY, F. R. C. S. Eng., B. A., M. B., B. C., Cantab., Senior Surgeon, St. Mark's Hospital for Cancer, Fistula, and other Diseases of the Rectum; The Queen's Hospital for Children, London, etc. Fourth Edition. New York: William Wood & Co., 1916. Pp. viii-275. (Price, $2.25.)

No subject in surgery requires such explicit directions as aftertreatment of operations, and no subject is so neglected in the textbooks. Any book by an experienced surgeon on this part of surgical technic should be welcomed by those into whose hands the details of aftertreatment fall. This is true, not so much of the general surgeon and special surgeon, who requires no textbook to instruct him in this subject, but rather the general practitioner and hospital intern. That a want has been felt for a book of this kind is shown by the appearance of this fifth edition. New chapters of special interest in the present volume are those on the treatment of gunshot wounds and on surgical shock. Both have been brought up to date, and represent the prevailing views and practice of today. The book covers the most practical and common operations of general surgery. All unnecessary references to the literature and the practice of other than the author's clinic have been wisely eliminated.

A Textbook of Fractures and Dislocations. With Special Reference to Their Pathology, Diagnosis, and Treatment. By KELLOGG SPEED, S. B., M. D., F. A. C. S., Associate in Surgery, Northwestern University Medical School; Associate Surgeon, Mercy Hospital; Attending Surgeon, Cook County and Provident Hospital, Chicago, Ill. Illustrated with 656 Engravings. Philadelphia and New York: Lea & Febiger, 1916. Pp. viii-888. (Price, $6.)

The subject of fractures has for many years been in such a transition period, particularly as regards treatment, that any new work covering this field is of special interest. The subject has become so broad and the details of diagnosis and treatment are so complicated, especially since the advent of the x ray and operative methods, that it has become a specialty in itself. The author brings to the present work a great deal of study and practical work, and the book has a distinctly personal character. The practice of others is given in lesser detail, while the author's methods, which he has found useful by experience, are described minutely. His views on the present status of the operative treatment of fracture are stated clearly and with authority.

The subject of dislocations is treated in conjunction with fractures, which seems a better arrangement than putting them in another part of the book, as the two are frequently combined in traumatisms. The drawings from x ray plates and other illustrations are clear and helpful. The x ray plates themselves are not as numerous as we should like.

Transactions of the College of Physicians of Philadelphia, 1915. Edited by WALTER G. ELMER, M. D. Volume 37, Third Series. Pp. 500.

The volume contains the papers read before the College from January to December, 1915, inclusive, the annual address of the president and a list of the Fellows of the college. The various articles are well written, the authors being among the foremost of the medical profession in the United States. Every branch of medicine and surgery, as well as public health work and military hygiene, is dwelt upon. The proceedings of the section in ophthalmology are given in full. The appendix contains the annual report of the library committee for the year, and a list of the prizes and lectures.

Interclinical Notes

In the *Outlook* for July 19th there is a letter in which it is stated that even a jellyfish will fight; the most harmless looking of the tribe seem to be able to sting most severely. The writer's idea was probably that although we, as a nation, look harmless, we could, on occasion, deliver most lethal blows. But while we were trying to prepare, zeppelins would be destroying our powder plants and gun foundries, would they not? Again, if you fight the jellyfish with a stick, you run no danger of shock.

* * *

Current Literature for July begins with a survey of the mysterious expedition to the Mexican border of our militia, and then proceeds to discuss the candidates for the next presidential election. After a glance at European politics, there are biographical sketches of Schiff, Hellferich, and Jonescu, an extract from *Youth*, "a dramatization of the young dramatist," an allusion to Indian music and to new European music, the latter being most revolutionary. Science and Discovery, Religion and Social Ethics, Literature and Art, and the Business World, the usual departments of this invaluable monthly, are entertainingly filled and will afford the reader the interest and instruction to which he is accustomed.

* * *

The *Survey* for July 8, 1916, describes the new school for the study of tuberculosis established at Saranac Lake in memory of the late Dr. Edward L. Trudeau. Universal State reciprocity in the practice of medicine is also discussed under the heading, Interstate Shingles for the Doctors. It gives a list of the physicians appointed by the late Dr. William L. Rodman to form an interstate board of examiners. They were: Admiral W. C. Braisted, surgeon general of the navy; Commander E. R. Stitt, of the navy;

Surgeon General W. C. Gorgas, of the army; Colonel L. A. LaGarde, of the army, treasurer; Surgeon General Rupert Blue and Assistant Surgeon General W. C. Rucker, of the Public Health Service; Dr. Herbert Harlan, representing the Federation of State Medical Boards; Dr. Isadore Dyer, of New Orleans; Dr. Victor C. Vaughan, of Ann Arbor, Mich.; Dr. Henry Sewell, of Denver; Dr. Louis B. Wilson, of Rochester, Minn.; Dr. E. Wyllys Andrews, of Chicago; Dr. Horace D. Arnold, of Boston, and Dr. Austin Flint, Jr., of New York.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers in the United States Public Health Service for the seven days ending July 12, 1916:

Collins, R. H., Scientific Assistant. Directed to proceed to Union City, Tenn., for duty in studies of rural sanitation in Obion County.

Eager, J. M., Surgeon. Granted one month's leave of absence on account of sickness, from July 7, 1916.

Frances, Edward, Surgeon. Directed to proceed to New York city for duty in investigation and suppression of poliomyelitis.

Frost, W. H., Passed Assistant Surgeon. Directed to proceed to New York city for duty in investigation and suppression of poliomyelitis; granted three days' leave of absence from July 4, 1916.

Harralson, M. F., Scientific Assistant. Ordered to proceed to Greenville, S. C., for duty in studies of rural sanitation in Greenville County.

Hunter, Edward R., Scientific Assistant. Ordered to proceed to Liberty, Mo., for duty in studies of rural sanitation.

Lavinder, C. H., Surgeon. Directed to take charge of Service operations in aid of the State and municipal health officers in the investigation and suppression of poliomyelitis in New York city.

Leake, J. P., Passed Assistant Surgeon. Directed to proceed to New York city for duty in the investigation and suppression of poliomyelitis.

Lumsden, L. L., Surgeon. Directed to proceed to Birmingham, Ala., for conference with health authorities relative to the typhoid situation in that city.

Oakley, J. H., Surgeon. Bureau letter dated June 14, 1916, granting three days' leave of absence from June 17th, amended to grant two days' leave of absence from June 17th.

O'Brien, Henry R., Scientific Assistant. Directed to proceed to Liberty, Mo., for duty in studies of rural sanitation.

Parran, Thomas, Scientific Assistant. Directed to proceed to Liberty, Mo., for duty in studies of rural sanitation.

Pettus, W. J., Surgeon. Granted leave of absence for one month and six days with pay from July 17, 1916, and twenty-four days without pay from August 23, 1916.

Reuter, F. A., Scientific Assistant. Directed to proceed to Liberty, Mo., for duty in studies of rural sanitation.

Ridlon, J. R., Passed Assistant Surgeon. Directed to proceed to New York City for duty in the investigation and suppression of poliomyelitis.

Rucker, W. C., Assistant Surgeon General. Directed to proceed to New York for conference relative to preventive measures to be taken against the interstate spread of poliomyelitis.

Sanders, Morris B., Scientific Assistant. Directed to proceed to Union City, Tenn., for duty in studies of rural sanitation in Obion County.

Sayers, R. R., Assistant Surgeon. Directed to proceed to Jefferson City, Mo., for duty in studies of rural sanitation in Clay County.

Stewart, P. M., Assistant Surgeon. Directed to proceed to Liberty, Mo., for duty in studies of rural sanitation in Clay County.

Stiles, C. W., Professor. Directed to proceed to New York for conference with health authorities with respect to the influence on health of certain articles of food.

Wilson, J. G., Assistant Surgeon. Ordered to report to Surgeon C. H. Lavinder for duty in the investigation and suppression of poliomyelitis.

Promotions.

Passed Assistant Surgeon Francis H. McKeon, promoted and commissioned as a surgeon, effective May 13, 1916.

Passed Assistant Surgeon E. A. Sweet, promoted and commissioned as a surgeon, effective May 10, 1916.

Assistant Surgeon C. L. Williams, promoted and commissioned as a passed assistant surgeon, effective May 23, 1916. July 3, 1916.

Boards Convened.

Board of commissioned medical officers reconvened at the Bureau, Washington, D. C., July 10, 1916, for the examination of applicants for appointments as assistant surgeon. Detail for the board: Assistant Surgeon General W. C. Rucker, chairman; Surgeon E. A. Sweet, member; Passed Assistant Surgeon J. R. Hurley, recorder. Surgeon John S. Boggess and Passed Assistant Surgeon B. H. Earle detailed for duty on a Coast Guard Retiring Board at the Marine Hospital, Port Townsend, Washington, July 17, 1916. Surgeon J. A. Nydegger and Surgeon C. W. Vogel detailed for duty on a Coast Guard Retiring Board at the Marine Hospital, Baltimore, Md., July 10, 1916.

Births, Marriages, and Deaths

Born.

Grant.—In Seattle, Wash., on Monday, June 26th, to Dr. and Mrs. E. E. Grant, a daughter.

Talbot.—In Brookline, Mass., on Tuesday, June 27th, to Dr. and Mrs. Fritz B. Talbot, a daughter.

Married.

Herrick-Dickson.—In Santa Rosa, Cal., on Tuesday, June 27th, Dr. Albert B. Herrick, Jr., and Miss Helen Dickson.

Parris-Smith.—In Brookline, Mass., on Wednesday, June 14th, Dr. Roland O. Parris and Miss Julia Estes Smith.

Richards-Gibbs.—In Salt Lake City, Utah, on Monday, July 3d, Dr. Ralph Richards and Miss Rhoda Gibbs.

Upshaw-Campbell.—In St. Louis, Mo., on Tuesday, June 27th, Dr. Harry I. Upshaw and Miss Flora Caroline Campbell.

Young-Ewen.—In Barre, Vt., on Thursday, June 29th, Dr. George A. Young and Miss Clara Ewen.

Died.

Baker.—In Owego, N. Y., on Sunday, July 9th, Dr. Merritt T. Baker.

Barnes.—In Stratham, N. H., on Thursday, July 6th, Dr. Edward M. Barnes, aged fifty-eight years.

Bonnett.—In Leroy, Ill., on Friday, July 7th, Dr. J. Y. Bonnett, aged forty-three years.

Carter.—In Hartford, Conn., on Tuesday, July 4th, Dr. Henry Carter, of Manchester, aged forty years.

Dean.—In Atlanta, Ga., on Tuesday, July 4th, Dr. E. W. Dean, of Hiram, Ga.

Denny.—In Kingston, N. C., on Saturday, July 1st, Dr. W. W. Denny, aged eighty-three years.

Gale.—In Roanoke, Va., on Wednesday, July 5th, Dr. Joseph A. Gale.

Gray.—In Batavia, N. Y., on Thursday, July 6th, Dr. Clarence V. Gray, aged fifty years.

Henderson.—In Detroit, Mich., on Tuesday, July 4th, Dr. Thomas Henderson, aged sixty-one years.

Henry.—In San Jose, Cal., on Wednesday, June 28th, Dr. Joseph W. Henry, aged forty-seven years.

McDonald.—In Concordia, Kan., on Friday, June 30th, Dr. W. H. McDonald, aged seventy-two years.

Phillips.—In Port Arthur, Tex., on Monday, July 3d, Dr. J. C. Phillips.

Roan.—In Jones, Ga., on Friday, June 30th, Dr. James T. Roan, aged sixty-four years.

Selvage.—In Newark, N. J., on Friday, July 7th, Dr. Charles Edwin Selvage, aged thirty-two years.

Sorrel.—In Washington, D. C., on Friday, June 30th, Dr. Francis Sorrel, aged eighty-nine years.

Smith.—In Auburn, Me., on Saturday, July 8th, Dr. Roscoe Smith, aged eighty years.

Winkler.—In Applecreek, Ohio, on Thursday, July 6th, Dr. W. H. Winkler, aged seventy-two years.

Original Communications

MEDICAL WOMEN,

In History and in Present Day Practice,

BY MARY SUTTON MACY, M. D.,

New York,

Neurologist, Demilt Dispensary.

Ever since Eve was sufficiently philanthropic to share the legendary apple (which some say has proved to be a lemon) there have been more or less heated and strenuous arguments anent "woman's place" in one or another field of activity, and the year 1915 A. D., not to be outdone by its predecessors, has furnished a more or less acrimonious discussion on "woman's place in medicine." One of our medical brethren from the Athens of America, is reputed to have cast unchivalrous reflections upon the capacity of women for other than social service, and about his remarks, as reported in the daily press, has waged a war of words in which, strange to relate, the women have been noted for their silence. It was not my intention to break this strange and unnatural feminine silence, in which I may admit I was taking an unholy joy, as I knew the fires were smouldering beneath, but at the earnest solicitation of the editor of the NEW YORK MEDICAL JOURNAL I have consented to attempt to comply with his request, i. e., "we should like to publish an original communication showing what women physicians have accomplished since they first began the study of medicine." Being convinced that the editor had asked for more than he meant to, I tried to escape on the plea of the antiquity of women—a curious anomaly surely—in the medical world, but, being a true sportsman, the editor refused to let me off on any such excuse, and so the following account must be credited to its true origin and not blamed on the daughter of Eve who awards the apple.

In his essay on the history of medicine, Jurisconsult Tiraquean says: "There have been a large number of physicians who have been numbered among the saints; several pontiffs, emperors, and kings have practised medicine; also queens and other women of quality," and at the conclusion of his essay he gives particulars of the standing of such persons as have been devoted to medicine, arranging the list in alphabetical order. To this interesting and instructive list those who are genuinely concerned as to the standing of the "antique women" in medicine are most cordially referred. For our purpose we may begin the narrative with the historic daughter of Aetes, King of Colchis, who practised in her father's court, 1228 B. C., making a specialty of antidotes for poisons, which undoubtedly was one of the most important, if not the most important specialty of the age. Hygeia, later deified in Greece, was a daughter of Æsculapius and presided over the temple devoted to the sick at Epidaurus. So long as the practice of medicine formed a part of the priestly functions, as in ancient Egypt, the crafty guardians of superstition sedulously concealed their superior knowledge from the ignorant people. Yet there were priestesses in the Egyptian temples and the story of Moses shows that female gynecologists were not unknown to the Egyptians of his time. Coming down the centuries a little, an Athenian maiden, Agnodice, born 506 B. C., calls for special attention as an illustration of how curiously history sometimes repeats itself. Agnodice was very desirous of becoming a doctor, but even in those days there were obstructions, not dissimilar to those met by the women of later days whom we refer to as pioneers, such as Elizabeth Blackwell in America, Miss Jex Blake and Mrs. Garrett Anderson in England, and others. Agnodice, of Athens, was duly informed, and seemingly impressed, by the fact that her sex was an insuperable obstacle and, being unable to force her way into the medical professsion of her native Athens, tried another plan. Artfully disguising her sex, she found no difficulty in being taught midwifery by a very eminent anatomist and physician of the day named Herophilus, but her story only begins with her success in gaining her education and the privilege of practice. Trusting in the loyalty of her sisters she is reported to "have whispered her secret to her shrinking patient" always when called to a case. That her confidence in women was not misplaced was speedily proved; her secret was kept inviolate and her practice grew with such astonishing rapidity that her confrères became jealous—verily; how history does repeat itself—and finally they accused her of corrupt practices and brought her to court. Agnodice had gained confidence with her success, she frankly revealed her sex to the Areopagus and it was promptly recognized as the reason for her large connection among women, who naturally preferred a woman near them at such a time. As a result of her trial, a law was immediately passed allowing all free born Athenian women to learn midwifery. So the battle was won in Athenian days.

Not all the women in medicine of antiquity were

of the type of Agnodice, however; one of the most distinguished, certainly the most infamous, and perhaps, therefore, the most famous woman of the ancient medical world was Cleopatra, Queen of Egypt, who lived about a half century before the Christian era. She was a most accomplished, a learned, and, according to accounts, a beautiful woman to whose toils of grace and attractions of person, Julius Cæsar, Mark Antony, and other men of her day fell easy victims. She is reported to have compounded cosmetics and to have written on the art of preserving beauty. Galen is authority for the fact that she wrote books on the diseases of women. At least she gave her name to them, and while it is probable that she wrote them, she declared in their prefaces that they were written by her sister Arsenoe—whom Antony, at his mistress's bidding, caused to be put to death. Be that as it may, the volumes have not come down to us and we cannot therefore judge of their professional value.

The medical school of Pythagoras was carried on, after his death, by his wife with the aid of her two sons, and she was the author of several medical treatises which were authoritative for many years. Pliny, in his natural history, mentions Olympias the Theban, a woman who was the author of many well known prescriptions; Salpe, another woman who wrote on remedies for the diseases of women, and Sotira, a woman to whom is attributed a prominent treatise on the treatment of fevers.

No fewer than four saints, who were also physicians and women, are mentioned as living before 500 A. D., and two of these, St. Zenais and St. Philomela lived in the first century. They were natives of Tarsus, but left their home and devoted their lives to medical science and the conversion of their patients to Christianity. They were kinswomen of St. Paul the Apostle; the tradition says that that chronic woman hater was always attended in his many illnesses by St. Zenais.

Galen mentions Antiochus especially, who lived in the second century and whose statue was found in the ancient town of Tlos in Asia Minor, bearing this inscription: "To Antiochus, daughter of Diodotos of Tlos, the council and commune of the town of Tlos, appreciating her medical skill, raised this statue to her at their own expense."

Among other medical women of early Christian times in Rome are found such as Aspasia, who as Herrgott points out, was the originator of podalic version, Theodosea, mother of St. Procopus, who practised general medicine and was executed about 312 A. D., and Fabiola, A. D. 380, a medical woman not lacking in analogy to Florence Nightingale, and the founder of hospitals in Italy, during the time of the Emperor Julian, to whom this honor is, therefore, usually credited. Speaking of medical women saints, it is not possible to omit mention of St. Hildegarde, who lived in Germany, 1098-1179, and of whom Herwegen gives an interesting characterization. She wrote two medical books, *Liber ismplicæ medicinæ*, and *Liber compositæ medicinæ*. Schott, of Strassburg, in 1533, edited the first, under the title, *Physica St. Hildegardis*. This was discovered by Doctor Jessen in the library of Wolfenbuttel, and later he obtained from Copenhagen the manuscript entitled, *Hildegardis curæ et causæ*, which he was convinced, after a careful examination, was the second medical work of the saint. It is in five books and treats of general divisions of created things; of the human body and its diseases; and of the causes, symptoms, and treatment of illnesses.

In Norse saga and Teutonic legend many women are celebrated as surgeons and physicians, and the parting gift recorded of the Queen given to Princess Ysolde, when she "leaves her native Ireland to become the wife of Cornwall's King," is a chest of drugs, philtres, and poisons; and it was Ysolde's fame as a physician which indirectly brought her to the attention of King Mark. Under Mohammedan rule, in the Middle Ages, women were placed in excessive isolation, and we find that several women were skilled in attending to the requirements of their sex. Albucasis, of Cordova, one of the most skillful surgeons of the twelfth century, secured the services of several women properly instructed as assistants and placed them in charge of operations on women, especially gynecological operations. Avicenna, writing of remedies for the eye diseases then so common, mentions a collyrium compounded by a "woman well versed in medical science." In Madrid in 1587 appeared a learned medical work entitled *Nueva Filosofia de la Naturaleza del Hombre* by a woman physician named Olivia del Sabuco.

The edict of the faculty of Paris, which forbade the practice of medicine to all who were not members of that body, to which only unmarried men were admitted, was such a dead issue as long ago as 1292, that eight women physicians were established in Paris at that time. The archives of Frankfort-on-Main mention fifteen women—three of whom were oculists—as established between the years 1389 and 1497. In the southern part of Italy, where Grecian influence was strongest in the Middle Ages, at Salerno, was founded the first medical school of modern times. Here the department of diseases of women was entirely handed over to women physicians, and we have a number of distinguished women professors who wrote textbooks, thought, and taught in the school. One of them, Trotula, was the author of a work entitled *De passionibus mulierum ante, in et post partum*, in which she describes perineorrhaphy and advocates its performance immediately after labor. She became famous all over Europe in her time. Among other Salernian medical women were Abella, Costanza Calendula, Mercieriade, author of several treatises, Rebecca Guarna, and Adelomota Maltraversa. Another Salernian woman physician of great prominence was Marguerite of Naples (or of Sicily), who was called to Poland and practised in the court of King Ladislaus (who died in 1414). Of this period of medical practice Doctor James J. Walsh has aptly said: "It would be easy to think that after all feminine education in medicine must have meant very little at this time, for the generation did not know much medicine. Anyone who thinks so, however, has the privilege of another thought after looking into the subject. That thought should come after due information. The surgery of Salerno particularly—and it is in this that most of us would be sure that the old times was very

backward—is an unending marvel. . . . The textbooks describe operations on the skull for tumor and abscess, on the thorax for fluid, on the abdomen for wounds of the intestines; they were treating hernias in the exaggerated Trendelenberg position and they had three methods of anesthesia, one of them by inhalation, and were using strong wine as an antiseptic and boasting of getting union by first intention."

In England, as long ago as the days of King Edgar (959-975), women were entitled by law to practise medicine, but in 1421 their male competitors petitioned Henry V, begging most piteously that women be not allowed to practise physic, and consequently the former laws were repealed, and we hear little more of medical women in England until Lady Anne Halkett (1622-1679).

After the so called Middle Ages the number of women physicians appears to have diminished everywhere, except in Italy where two women held professorships at the University of Bologna. One of the prosectors of Mondino, who is often called the Father of Modern Dissection, was a young woman, Alessandra Giliane, to whom must be credited the first attempts to inject anatomical specimens in order to preserve them. That her preparations might be more valuable and studied for a longer time, she colored the tissues variously, especially the arteries and veins. She died of blood poisoning, probably contracted in some accident in her carefully detailed dissection work. It is to another woman of Bologna, Anna Morandi Mazzolini, that must be credited the introduction of wax models into medical study, and she held the chair of anatomy at Bologna for nineteen years, and discovered the exact point of insertion of the oblique eye muscles, and though she received tempting offers from other Italian universities and even from England and Russia, she preferred to remain in her native city of Bologna. She enjoys the distinction of being the first "to reproduce in wax such minute portions of the human body as the capillary vessels and the nerves." Her collection of anatomical models is still to be seen at the Institute of Sciences. Contemporary with Anna Morandi Mazzolini was Laura Caterina Bassi, who studied physiology and medicine with Taccone, mathematics with Manfredi, and natural philosophy with disciples of Gassendi. She was appointed to the chair of physics and a medal was struck in her honor by the Senate. She held her professorship for twenty-eight years, marrying in the meantime a physician, J. J. Veratti, to whom she bore twelve children. She died in 1778 at the age of sixty-seven years.

In 1799, Maria Della Donne appears as professor of medicine and obstetrics at Bologna, and although a number of prominent women should be noted at other Italian universities throughout the Renaissance period, we have space to mention only a few. Dorotea Bocci (1436) succeeded her father in the chair of philosophy at Bologna, and also in the practice of medicine: Zaffira Ferretti, M. D., Marie Petruccini, Maria Sega, M. D., Novella Calderine, and Madalena Buonsignore should be mentioned among the numerous women graduates of Padua, Pavia, Ferrara, and other Italian universities. While women studied everything else at the Italian universities, as well as medicine, the custom evidently did not obtain in the north and west, apparently because Paris, whose influence meant so much to the others, was disturbed in its normal progress by the incident of Abélard and Héloise. The doors of the Paris school of medicine remained closed after this until opened in 1867 by Mary Putnam, later famous as Dr. Mary Putnam Jacobi. The Italian universities were never closed to women and by state decree, in 1876, all of them (fifteen in number) were *formally* opened to them.

In England, as we have said, the earlier liberal laws were repealed in 1421, but women appear to have continued in the practice of midwifery and gradually to have acquired a certain amount of recognition in the medical field, because in the seventeenth century, Anna Wolley and Elizabeth of Kent were occupied with the preparation of drugs and each of them published works on medical subjects. About this time, too, Elizabeth Lawrence, wife of the Reverend S. Berry, of Bristol, was living and admirably instructed in anatomy and medicine.

In this century, Peter Chamberlain introduced midwifery forceps and their use required the calling of a trained physician by the midwives. We are told that the first personages of the land consulted Lady Anne Halkett (born 1622), at this time, who became celebrated both for her proficiency in the theory of medicine and her skill in surgery. She cared for the wounded after the battle of Dunbar (1650) and was thanked by the King. Her reputation spread and reached Holland where she was also in demand. A staunch loyalist, she, with her family, suffered much in the cause of Charles I, but, notwithstanding her practice of medicine, her fame, and her misfortunes, she found time to write and have published no fewer than twenty-one books. In 1642, women were licensed as midwives at Chirurgeon's Hall after they had passed three examinations, but later in the same century they were referred to the Doctor's Commons for their license and thus lost their official connection with the medical world. It is of interest, however, to note that Victoria was the first English queen to depart from the royal custom of employing women midwives. Her reason for so doing was a generous one; many women objected on religious and other grounds to the alleviation of labor pains by the use of chloroform, and the Queen decided to lend the weight of her example in favor of its use. As its administration required a fully qualified doctor, and there was none such among the women midwives of the day, Victoria departed from the time honored royal custom and employed a medical man.

By special decree of Frederick the Great, the University of Halle, in 1754, granted a medical degree to Frau Dorothea Erxleben—said to be the first in the history of any German university—and later Giessen granted degrees as doctor of obstetrics, in 1816, to Frau von Siebold, who officiated at the birth of Queen Victoria of England, and, in 1809, to Frau von Heidenreich, the daughter of Frau von Siebold. While women in medicine were wanting in France from the days of Héloise to the present era (1867), there were two women workers in anatomy there and many midwives such as Louise Bourgeois, Marguérite de la Marche, Madame La Chapelle, and

Madame Boivin, who wrote extensively and after publishing a work on *Hydatid Mole* was made an honorary M. D. by the University of Marburg.

The Countess of Cinchona, a medical woman, wife of the Viceroy of Peru, will always be remembered as the introducer in 1640 of quinine for the treatment of malaria. And it was a Swiss woman, Madame de Hilden, who first removed a piece of steel from the eye by the use of a magnet, and she also planned many other operations whose technic is followed today. She assisted and advised and finally replaced her husband in his surgical work.

Turning to the American colonies, we should hardly expect to find women practitioners of much fame in a community where there were no medical colleges, and even the best of men were of little account prior to the Revolutionary War. Doctor Martha Wollstein says: "In the American colonies the history of medical women began deplorably, for it is recorded that the first person to be executed in the colony of Massachusetts Bay was one Margaret Jones, a female physician accused of witchcraft." Mayhap, however, the name Jones was too much for the unfortunate woman, or else Massachusetts became more tolerant later, for we find a woman practitioner obtaining fees, which must have been enormous for those days, if we are to believe the account book of one Reverend Timothy White, of Nantucket, who under date of June 21, 1749, writes: "Pd. to Mary Barnard, Doctr., £5 1s 8d, and for Physick then had 2 shillings." In the famous blue laws of Connecticut occurs the following entry under date of March, 1638: "Jane Hawkins, the wife of Richard Hawkins, had liberty till the beginning of the third month called May, and the Magistrates (if shee did not depart before) to dispose of her; and in the mean time shee is not to meddle in surgery or phisick, drinks, plaisters, or oyles, nor to question matters of religion, except with the Elders for satisfaction." On the other side of the picture in Connecticut we learn that the town of Torrington, in Litchfield county, had as early as 1773 two women, Mrs. Jacob Johnson and Mrs. Huldah Beach, who were greatly honored on account of their remarkable skill as accoucheuses. Mrs. Johnson, or Granny Johnson as she was called, "rode on horseback, keeping a horse for the special purpose, and travelling night and day, far and near," and was as thoroughly known and trusted as was ever any physician in the town. The celebrated Anne Hutchinson began her career as a midwife, and in the town records of Rehoboth is mentioned the arrival, on July 3, 1663, of Dr. Sam Fuller and his mother, he to practise medicine, she as midwife, "to answer to the town's necessity, which was great." Thomson's *History of Vermont* sketches the career of Mrs. Thomas Whitemore in the town of Marlboro, in 1765, who is described as being "possessed of a vigorous constitution and frequently travelling through the woods on snow shoes from one part of the town to another by night and by day, to relieve the distressed." "This sturdy woman," says Dr. Mary Putnam Jacobi, "lived to be eighty-seven years of age, an ironical comment on the theory of necessary deficiency of endurance in the female sex."

During the colonial period the medical profession of the country remained disorganized and there was no effort made, for more than 150 years after the first settlement, toward improving the medical practice of the country or the education of physicians. Thatcher says: "No medical journal was published in America until toward the close of the eighteenth century. . . . The first anatomical dissection was made in New York in 1750." During the Revolution the medical conditions were shocking, but it served to bring the profession out of obscurity, encouraged and stimulated foreign travel for the purpose of study, and breathed into the American fraternity the first breath of medicine as a science. Dr. Mary Putnam Jacobi quotes from the *Remarks of a Boston Physician of 1820:* "It is one of the first and happiest fruits of improved medical education in America that females were excluded from practice." Verily again history repeats itself, even Boston history! Or can it be possible that there is something in the atmosphere of that Hub of the Universe which so distorts the masculine vision? Dr. James J. Walsh, of New York, has said: "Flinders Petrie, the great English Egyptologist, has suggested that there are seven great phases of culture in humanity in which men reached a climax of achievement and intellectual power and then decadence began. In each of these phases we are able to trace a significant development of feminine influence. . . . As women become interested in the intellectual life, they have been prone to withdraw more and more from the simple, natural, womanly duties which they must assume, or they will not be fulfilled. Only women can be mothers, and unless they are mothers the race does not go on. Whenever women have become much interested in the intellectual life, first, there has developed a sad disinclination to matrimony. Apparently, woman only needs to know man well not to think much of him. . . . Then the intellectual women who marry have ever smaller and smaller families." This reflection of Doctor Walsh's may serve as a partial excuse for the present day attitude of our "Boston brother," but it would hardly do for the Boston physician of 1820 when large families of children were still the rule throughout the country, the "bachelor maid" was as yet unheard of except under the less chivalric title of "old maid," and even the woman suffrage movement was in the germ. Incidentally Doctor Walsh's attention might be called—though the case may be an isolated one—to the family which Professor Laura Caterina Bassi bore to her medical husband, J. J. Veratti, in the eighteenth century (*vide supra*). "If this be treason!"——

Allow me a further quotation from Dr. Mary Putnam Jacobi: "A startlingly long step was taken at a stride, when, thirty years after the pæan of victory had been sounded over the complete suppression of female midwives, so that not even this corner of possible medicine might remain in possession of women—that then, half a dozen women, unknown to each other, and widely separated in this immense country, should appear almost simultaneously upon the scene and demand the opportunity to be educated as full physicians." Doctor Jacobi goes on to speak of these women. Harriet K. Hunt, of Boston, who, refused permission to attend lectures at Harvard in 1847, made a second application there in 1850, on which five out of the seven mem-

bers of the faculty voted "that Miss Hunt be admitted to the lectures on the usual terms, provided that her admission be not deemed inconsistent with the Statutes," and a week later the president and Fellows of the university announced that the statutes of the medical school offered no obstacle to the admission of female students. At a general student meeting, however, resolutions were adopted remonstrating against the "amalgamation of sexes and races"—a few colored students had been admitted at the beginning of the session—and the faculty, fearing, perhaps, that the majority of the students might withdraw to Yale, bowed to the storm and advised the "female student" to withdraw her petition, which she did. Thus we see another chivalric instance—and, strangely, again it is from so close to Boston—and the odd idea is advanced "that whenever a woman should prove herself capable of intellectual achievement this latter would cease to constitute an honor for the men who had previously prized it. Hence the urgent necessity of excluding women from all opportunity of trying." The Blackwell sisters were led to the study of medicine practically from economic reasons which compelled them to do something to earn their daily bread, and as Dr. Emily Blackwell subsequently explained, "We realized the infinite narrowness and pettiness of the avenues open to women and the crowds of competitors who kept each other down in the struggle. We determined that we would endeavor to open a new door and tread a fresh path rather than push for a footing in one already filled to overflowing." It was in 1845 that the plan of studying medicine became a settled resolution with Elizabeth Blackwell, and she was thus the real originator of the idea and movement in America. Marie Zakzrewska, a young German woman and a favorite pupil of Doctor Schmidt, one of the State examiners of the Berlin School of Midwives, was the fourth woman of this group of the advance guard of women physicians in America, whither she came in 1853, and through the kindness of Elizabeth Blackwell learned English and secured admission to the medical school at Cleveland. After obtaining her degree she was associated for a time with the Blackwell sisters and then went to Boston, where she subsequently became identified with the second hospital in this country to be conducted by medical women, i. e., the New England Hospital founded in 1862. The fifth of this group of pioneers was Anne Preston, a Quaker lady of Philadelphia, who was identified with the movement to create a woman's medical college in Philadelphia, and the sixth annual announcement of the school mentions Doctor Preston as professor of physiology. Dr. Emmeline Cleveland, a graduate of this Philadelphia school, went to the Paris Maternité to fit herself to lecture upon obstetrics, thus repeating for the women, nearly a century later, the careers of Dr. James Lloyd, of Boston, and Doctor Shippen, of Philadelphia (in 1752 and 1762 respectively), who went to England to obtain knowledge from which to lecture on obstetrics and returned to organize the science for the men of the colonial medical profession. The sixth of this pioneer group, Sarah Adamson (the second woman in the United States to receive a medical diploma), married one year after her graduation a Doctor Dolley, of Rochester, N. Y., in which city she at once settled and practised successfully for thirty-eight years, from 1852 till 1890, after which she retired. Doctor Dolley, like the Blackwell sisters, died only within the last few years, much beloved and honored by the women who have followed in the path they blazed so ably and at such great personal cost.

It is not possible in an article such as this to give a history of all these splendid pioneer women and what they have accomplished. Many abler pens have written the histories of their lives, which to a great extent were paralleled a few years later in England. The story is perhaps most briefly told by Dr. Martha Wollstein, from whom I cite many of the following facts: "The history of women in medicine since 1849, when Dr. Elizabeth Blackwell graduated at Hobart College, Geneva, is a familiar tale that cannot be told too often. How she was refused permission to study at all colleges in Philadelphia and New York, until finally the faculty at Geneva put the matter before the student body, and they voted to extend their unanimous invitation to her to become a member of their class" (shades of chivalric Boston, what is this!) Dr. Emily Blackwell has ably told the story of how she graduated at Cleveland after having been debarred from taking her second term at the Rush Medical College, Chicago, how the New York Infirmary was established in 1854-1857 with a dispensary and twelve beds for poor lying-in women and how the Woman's College of New York Infirmary was opened in 1865. "Of its close in 1899, when Cornell opened its medical course to women, we can only speak with regret." The Woman's Medical College of Pennsylvania had been founded fifteen years earlier, and was the first college in the world for the medical education of women. The Woman's Hospital in Philadelphia was founded in 1861, and in 1895 the hospital and dispensary of the alumnæ of the Woman's Medical College of Pennsylvania was opened, thus making of the proverbially slow Philadelphia a city sufficiently alert and progressive to be able to lay claim to the unique distinction of being the only one able to boast of two hospitals founded and run by medical women. In Chicago, in 1865, the Women's Hospital was founded under the guidance of Dr. Mary Thompson, and the Women's College followed in 1869, becoming in 1891 an integral part of Northwestern University. The fifth hospital run by women physicians, the Hospital for Sick Children and Women, was opened in 1875 in San Francisco, and the sixth is Northwestern Hospital in Minneapolis. New York and Boston each boast of a homeopathic medical school founded in 1863 (by Dr. Clemence Lozier) and 1874 respectively. With the opening of the State universities to women, beginning with the University of California, in 1869, and followed by every western State university, the necessity for special medical colleges ceased in the west, but in the east, excepting only Johns Hopkins (1893), Cornell (1899), Pennsylvania (1915), and Columbia (1916), no university of the first grade admits women to its medical school. Johns Hopkins, Cornell, the universities of Rochester, of Buffalo, Iowa, Illinois, Michigan, Minnesota, McGill, Edinburgh, Glasgow, Sidney, Adelaide, Stockholm, Paris, and Rouen have all had, or at present have

medical women in official teaching positions in their medical schools. New York University and Bellevue Medical College have for four years had two women as special lecturers to the undergraduates, which same women, this year (1916), held in addition salaried positions as lecturers to postgraduate students of the medical college.

Dr. Mary Putnam Jacobi was appointed clinical lecturer in children's diseases at the Post-Graduate Medical School in 1882, "the first time in this country that a lectureship in a masculine school was held by a woman." Dr. Sarah J. MacNutt was also a lecturer in diseases of children, and Dr. Grace Peckham Murray was professor of gynecology there. At the New York Polyclinic Hospital Dr. Rosalie Slaughter Morton has recently been made associate professor of gynecology with a staff of four medical women assistants. On the whole, however, there have been few opportunities for teaching open to the medical women outside of the special medical schools for women.

Mary Putnam—later Dr. Mary Putnam Jacobi—reopened to women the *Ecole de médecine* in Paris in 1867 and she and Miss Elizabeth Garrett—later Mrs. Garrett Anderson, M. D., dean of the London Medical School for Women—graduated there in 1871 and 1870 respectively. Miss Garrett was already registered as a licentiate of Apothecaries' Hall, London, since 1865, but at that time it seemed hopeless to obtain a medical degree from any of the British examining bodies, and so Miss Garrett had decided to study abroad. Elizabeth Blackwell had in the meantime been registered in London, in 1858, the first medical woman on the British register, and a group of plucky British women under the inspiration of Dr. Sophia Jex Blake were struggling to obtain a medical education in Scotland. Five women, Miss Sophia Jex-Blake, Mrs. Thome, Miss Pechey, Mrs. DeLacy Evans, and Miss Chaplin were trying to enter the medical class in Edinburgh University, and were joined by two more women, this group ultimately becoming known as the *Septem contra Edinem*.

In 1876 Dr. Sara H. Stevenson was admitted to the American Medical Association, the first woman to whom that national body of medical men opened their doors. Dr. Mary Putnam Jacobi had already, four years previously, gained recognition as a member of the New York County Medical Society, and in time she opened also the doors of other New York medical societies, such as the New York Academy of Medicine, New York Pathological Society, New York Neurological Society, etc., and, in 1874, she was a delegate to the New York State Medical Society. Dr. Garrett-Anderson was the first to obtain entrance to the British Medical Association and so on until general recognition and almost universal membership is accorded the women at the present time in every medical society or medical congress worthy of the name. A few special societies still hold to the narrow tendency of sex differentiation, but their influence is negative and their example generally looked upon with disfavor by the medical profession as a whole, which has recognized the ability of medical women.

(*To be concluded.*)

ANAPHYLACTIC FOOD REACTIONS IN SKIN DISEASES.*

With Special Reference to Eczema,

By Albert Strickler, M. D.,
Philadelphia,
Assistant Dermatologist, Philadelphia General and Samaritan Hospitals; Instructor in Dermatology, Philadelphia Polyclinic and School for Graduates in Medicine.

Of late years the study of foods and their relation to the health of the general economy has become more and more absorbing. It has been recognized that while food is absolutely essential to the life of the human structure, yet we are brought to the realization that not all varieties of foods are essentially beneficial to the human body; in fact, some types of food may prove very harmful to certain types or groups.

Foodstuffs may be divided into: 1, Proteins and albuminoids; 2, carbohydrates; 3, fats. Of these three varieties the proteins are capable of doing the greatest damage to the economy in susceptible individuals. One of the varieties of pathological phenomena which foods are capable of producing, finds expression in what is termed "food anaphylaxis," by which we mean a condition of unusual or exaggerated susceptibility of the organism to foreign proteins.

Probably the first recorded observation of hypersensibility was that of Jenner, when he wrote of an "efflorescence of palish color" about the parts where variolous matter had been injected into a woman who had had cowpox thirty-one years before. The first observation where the principles of anaphylaxis were used for diagnostic purposes, was that of Koch when he demonstrated the fact that tuberculous guineapigs are more susceptible to injections of tubercle bacilli than normal guineapigs, and that tuberculous guineapigs are markedly affected by tuberculin, while normal guineapigs are quite nonsusceptible. The early observations on anaphylaxis were made with serum injected into animals, and comparatively little attention has been paid to render animals anaphylactic by stomach feeding. Rosenau and Anderson succeeded in sensitizing guineapigs to horse serum injections by feeding horse meat and horse serum. Cow's milk, ox blood, and dried egg have been fed to guineapigs, and they have been rendered hypersensitive to these substances in from three to eight weeks.

From a study of experimental anaphylaxis the following deductions may be made:

1. There is a sensitizing substance of a proteid nature, which may be from serum, animal, or plant albumin, milk, egg albumin, and so on.

2. Injections may be made intravenously, intraperitoneally, subcutaneously, by cutaneous inoculation such as rubbing into abraded surfaces, and by mouth.

3. Before hypersusceptibility is detected, it is necessary for an incubation period to elapse between the first and second injection. This period varies from six to twelve days.

4. After hypersensibility is once established, it may persist for years, and can be transferred by heredity to posterity.

*Read before the Annual Meeting of the American Society of Immunologists, at Washington, D. C., May, 1916.

5. Within limits, sensitization is specific, being relatively but not absolutely so.

6. The constitutional phenomena of anaphylaxis may come on almost immediately, or not for five to six hours or so, and consist of respiratory disturbance, dyspnea, edema, tonic muscular spasms, glandular swellings, joint effusions, albuminuria, and hyperemic and urticarial skin eruptions. In severe reactions, the animal becomes excited, moves about from place to place, coughs, has respiratory distress, loses control of bowel and bladder, has convulsions, becomes paralyzed, and dies in respiratory failure.

7. Immediately following anaphylactic shock and repeated injections of the antigen in small doses, there is a state of immunity to anaphylactic shock from further injections of the same antigen. This state is called antianaphylaxis, and is absolute, although only temporary, and in this way is distinguished from immunity.

In our studies of food anaphylaxis the following proteins were employed: Cow casein, egg, beef and mutton, pork, fish, oysters, clams, crabs, wheat, oatmeal, rice, barley, tomato, and strawberries. The method of preparing these materials has been published in another paper. In brief, our method consisted in extracting the protein by use of a weak alkali, and, after shaking and incubating the solution, it was filtered, absolute alcohol was added, and the solution evaporated in a water bath. A saturated solution of this dry material was made in an alkalinized sodium chloride solution. This preparation was tested for sterility and also for its nitrogen content by the Kjeldahl method.

We adopted the endermic method of injecting our proteins, because it was felt that it was the more sensitive method. As a result of some experiments, which were published in another paper, it was concluded to use 0.1 c. c. as a standard dose. In none of our cases were there any evidences of constitutional reaction of any nature whatsoever.

We adopted the following standards as to what constituted a positive reaction: 1. The lesions must persist for more than twenty-four hours after the injections. In our practice we have fixed the standard as forty-eight hours. This period of time, to our mind, is the most important factor in reading the reactions, as it is in this way we obviate errors due to traumatism of injection and also rule out fleeting reactions of any irritant. 2. Next in importance is the presence of a distinct papule. 3. Third is the presence of erythema. 4. Fourth is the presence of tenderness at the point of injection.

In none of our cases was there any manifestation of soreness of the arm or glandular enlargement of the associated lymphatic glands.

Another method of performing these anaphylactic food tests consists in removing the upper layers of the epidermis of the flexor surface of the forearm in eight places, in two parallel rows of four, by rotation of a dental burr. Some of the abrasions are used for testing various proteins, such as milk, egg albumin, oatmeal, etc., and some are used as controls. It is stated that very rarely does the traumatism produce reaction. Patients vary, but as a rule the height of the reaction is seen in about thirty minutes. A positive result is the appearance of a papule, never wheal or vesicle. Various degrees of positiveness are observed. This method of food anaphylaxis has been studied by Doctor White, of Boston. From a study of fifty-six patients of varied ages suffering from eczema, he derives the following conclusions:

a. Eczema in children is due, in a certain percentage of cases, to excessive fat or sugar in their diet, or to egg albumin or milk, or in a minority of instances to diminished thyroid secretion. Approximately twenty per cent. of individuals afflicted with eczema are not sensitive to the common foods.

b. Normal people do not react to these tests.

c. Food anaphylaxis may be a factor in urticaria, and also possibly in acne vulgaris.

d. In eczematous individuals tested, approximately thirty per cent. of the controls were positive when this method was employed.

In the course of our experiments we studied the following diseases: 1, Eczema; 2, urticaria; 3, acne; 4, psoriasis.

We studied forty-six patients with eczema, and a great majority of them were kept under observation for some weeks. Our plan has been, whenever possible, to withhold local treatment entirely to see what benefit, if any, diet exerted on the course of the eruption, as to both subjective and objective phenomena.

From a study of Table 1 it can be seen that twenty-three patients, or fifty per cent., were in a greater or lesser degree benefited by changed diet, as shown by the anaphylactic food tests. In twelve cases, or twenty-six per cent., the food tests were entirely negative, and in the remainder the correction of diet, as shown by the food tests, did not have any bearing on the disease.

A few of the cases are worthy of comment:

Case I. Private patient consulted me about eight months ago for a recurrent erythematous eczema of arms and hands of four years' duration. He was under the care of a number of dermatologists, who advised him to discontinue his work. This eczema would come on every summer. He was a cabinet maker and was compelled to use glue which had to be in liquid form and was constantly subjecting himself to great heat. The anaphylactic food tests showed tomato +2, shellfish +1. These foods were discontinued and a cure resulted in about three weeks, with no recurrence up to date. After he was advised to discontinue tomatoes he volunteered the information, that as soon as tomatoes were in season, he would live practically on this article of diet, and almost coincident with this his eczema would recur.

Case II. Private patient; notes communicated to writer by courtesy of Dr. Jay F. Schamberg. Mrs. H. M., aged forty-five years, had suffered for fifteen years from an urticarial eczema, characterized by sheets of closely aggregated small papules accompanied by violent itching. The eruption was extremely fugacious, lasting about a day or two, then disappearing and shortly reappearing. The patient likewise suffered from nervousness and tremendous gaseous distention of the abdomen, with distressing colicky pains. She had consulted clinicians in New York city and Philadelphia over a period of years. The food tests gave a +4 cow casein reaction, and clam +2. Milk and milk foods were entirely eliminated from the diet. Within a few days the patient returned and said that a miracle had been performed. The abdomen had been reduced about four inches in diameter and at no time in years had she been so comfortable. The eruption had about ninety per cent. disappeared. The full extent of this improvement was not maintained in the subsequent weeks of observation, but the patient was infinitely better than she had been for many years.

Case III. A young lady, twenty-two years of age, consulted us at the Polyclinic Hospital for a recurrent ve-

TABLE I.

	Diagnosis.	Duration.	Extent.	Age.	Results of Food. Anaph. Tests.	Treatment.	End Results.
1	Erythem. eczema	4 years	Arms and hands	24 years	Tomato $+^2$ Shell fish $+^1$	Diet corrected and petrolatum locally	Cured in three weeks and remained so up to date
2	Eczema rubrum	4 months	Face	6 months	Cow Casein $+^2$	Put on broth and plain paste locally	Marked improvement. Shortly after withdrawal of milk lost from observation
3	Vesicular eczema	3 years	General	22 years	Cow casein $+^1$ Wheat (bread) $\pm$ Tomato $\pm$	Diet corrected; no local treatment.	Cleared up completely in ten days and has remained so
4	Vesicular squamous	7 years	General	9 years	Cow casein $+^2$	Diet corrected later; Lassor's paste applied locally	Itching disappeared completely in about four days and the skin showed marked improvement after one week; patient was discharged cured
5	Squamous eczema	7 weeks recurrent	Face, legs, and scrotum	25 years	Wheat $+^1$ Cow casein $+^4$ Mutton sugg. Shell fish	Diet corrected; no local treatment	Marked improvement after two weeks; patient reported later practically well
6	Vesicular eczema	5 years recurrent	Face and hands	16 years	Cow casein $+^3$	Diet corrected and simple ointment	Marked improvement on diet and simple ointment; later cured
7	Eczema seborr.	Unknown	Body	11 years	Cow casein $+^2$	Diet corrected; no local cal treatment	Cured in three weeks and discharged
8	Eczema erythem.	10 weeks	Body	42 years	Cow casein $+^2$ Mutton $+^1$ Fish $+^1$ Shell fish $\pm$	Diet corrected; also local treatment	Improved rapidly on diet and local treatment and was cured after three weeks
9	Papulosquamous	2 years	Arms and legs	50 years	Cow casein $+^2$ Clam $+^2$ Pork $+^1$ Mutton $\pm$	Diet and a mild lotion	Markedly improved
10	Eczema rubrum	3 weeks	Face		Negative to all tests	Kept on milk formula	Improved on local treatment and modified formula
11	Chronic urticarial eczema	9 years	General		Cow casein $+^4$ Clam $+^2$	Diet corrected	Very marked improvement in about ten days.
12	Squamous eczema	2 years	General	74 years	Cow casein $+^1$ Lobster $\pm$	Diet corrected	Subjective symptoms disappeared at once; skin condition not much improved
13	Squamous eczema	2-3 years	Buttock and face	5 years	Cow casein $+^2$ Egg $\pm$	Diet corrected	Itching ceased and rash markedly improved on diet alone
14	Vesicular eczema	3 months	Face, neck, and hands	43 years	Egg $+^1$ Cow casein $+^2$	Diet corrected and improvement was more rapid	Cured; diet, also local treatment
15	Dermatitis urticata	6 months	Both legs	39 years	Cow casein $+^1$ Tomato $\pm$	Diet corrected	Improved on diet alone, but not cured; afterward local treatment added
16	Vesicular eczema	3 years recurrent	Both hands	36 years	Cow casein $\pm$ Egg $\pm$	Diet corrected; patient abstained from meats for a long while	Slight improvement on diet alone
17	Eczema and onychia	Eczema 24 years; onychia 9 months	Eczema hands onychia of fingers and toes	55 years	Cow casein $+^2$ Mutton $+^1$ Beef $+^1$ Tomato $+^1$ Pork $+^1$	Diet corrected	Improvement on diet alone; was soon lost from observation
18	Vesicular eczema	9 months	Arms and hands	30 years	Cow casein $+^1$ Egg $\pm$ Oatmeal $+^1$	Diet corrected	Improved, but not cured on diet alone
19	Seborr. eczema	Several years	General	11 years	Cow casein $+$	Diet could not be carried out	Improving slightly on local treatment
20	Vesicular eczema	3-4 years recurrent	Hands	19 years	All tests negative		
21	Vesicular eczema		Hands	12 years	Cow casein $+^1$ Wheat $\pm$ Tomato $\pm$	Diet corrected	No improvement at all on diet
22	Erythematosquamous eczema	16 years	General	31 years	All tests negative		
23	Erythematosquamous eczema	8 years recurrent in summer	Arms, body, and legs	36 years	Egg $+^1$ Cow casein $+^2$ Beef $\pm$ Pork $+^1$	Diet corrected	No influence on eruption
24	Squamous eczema	9 months	General	33 years	Tests negative		
25	Vesicular eczema	2 months	Hands and feet	22 years	Cow casein $+$ Barley $+^1$ Tomato $+^1$ Wheat $+^1$ Mutton $+^1$	Diet corrected	Some improvement on diet; improved more rapidly on addition of local treatment
26	Vesicular eczema	5 years recurrent	Hands	27 years	Tomato $+^1$ Clam $\pm$	Diet corrected	No improvement
27	Erythematosquamous eczema	8 weeks	Legs	35 years	Wheat $+^1$ Cow casein $\pm$	Diet corrected	Lost from obesrvation
28	Papular eczema	3 years	Legs	28 years	Cow casein $+^4$ Fish $+^2$	Diet corrected	No improvement on diet
29	Seborr. eczema	6 weeks	Face and legs	31 years	Negative		
30	Seborr. dermatitis	4 weeks		22 years	Cow casein $+^1$ Beef $+^1$	Diet corrected	Lost from observation
31	Seborr. dermatitis	7 months	Face and ears		Egg $+^2$ Wheat $+^2$ Mutton $\pm$	Diet corrected	Slight improvement on diet alone and improvement more marked on addition of local treatment
32	Eczema	3-4 years recurrent	Arms, hands	56 years	Cow casein $+^3$ Beef $\pm$	Dict corrected	Some improvement on diet alone
33	Papular eczema	Some years	General	13 years	Negative		
34	Papulosquamous	3 months	Face and hands	60 years	Negative		
35	Seborr. dermatitis	8 years recurrent	General	52 years	Negative		Disease first originated from an attack of dermatitis venenata
36	Papular eczema	Unknown	Face and ears	19 months	Cow casein $+^2$ Egg $+^1$	Diet corrected	Improved markedly on corrected diet; relapsed when placed on prohibited articles of food
37	Squamous eczema	1 year	General	5 years			
38	Squamous eczema	22 years	General	64 years	Tomato $+^2$		Patient states that attack started while working in tomato patch
39	Squamous eczema	9 months	Legs and arms	65 years	Negative		
40	Erythematous eczema	3 weeks	General	34 years	Negative		
41	Papular eczema	6 months	Scalp and face	32 years	Negative		Cured by taking a vacation
42	Erythematosquamous	5 years	General	61 years	Negative		
43	Papular	3 months	General	47 years	Tomato $\pm$ Fish $+^2$		Lost from observation
44	Vesicular eczema	2 years recurrent	Hands	28 years	Mutton $+^1$ Cow casein $+^3$	Diet corrected	No improvement
45	Eczema	18 months	Legs	54 years	Beef $\pm$ Pork $\pm$ Cow casein $+^3$	Dict corrected	Lost from observation
46	Vesicular eczema	Several months	Hands	38 years	Negative		

sicular eczema of three years' duration. The eczema involved hands, arms, legs, and body in patches. Her food reaction showed cow casein +1, bread ±, tomato ±. After being placed on the corrected diet without local treatment, her skin cleared up in ten days and remained so for several months.

Case IV. Patient, nine years of age, under our service in the Philadelphia Hospital. She was afflicted with a vesiculosquamous eczema of seven years' duration, involving her entire body. The tests showed cow casein +2; milk, butter, cheese, and all foodstuffs containing milk were withdrawn from the diet. Her subjective symptoms cleared up in four days and the skin began to improve. She did not get any local treatment except petrolatum. Later she was put on Lassar's paste in addition to her diet, and was discharged from the hospital cured.

Case VIII. Private patient, referred by Doctor Falls, aged forty-two years, diagnosis, erythematous eczema of ten weeks' duration, involving the body. The food tests showed cow casein +2, mutton +1, fish +1, shellfish ±. Her diet was corrected and she received some local treatment and in about three weeks was well. When her diet was modified, she stated that her general health improved. She had more ambition to work, she was less nervous, and her shortness of breath was completely gone; in fact, she felt like a different woman. Without our consent she went back to her old diet, and in about three days she had a recurrence of her skin trouble, which disappeared promptly after taking a purge. She is still on the diet, and is feeling fine, without evidence of eczema.

Case IX. Private patient, referred by Doctor McDevitt, aged fifty years, papulosquamous eczema of two years' duration, involving arms and legs. Food tests showed cow casein +2, clam +2, pork +1, mutton ±. His diet corrected, and a mild lotion given, he showed prompt improvement both as to subjective and objective symptoms. By mistake he ate pork and beans and the next day a new crop of papules developed, which subsided on taking a purge. This patient had been suffering four years with constipation, and his condition has shown great improvement since he was on this diet.

URTICARIA.

We studied ten patients with urticaria, with the following results:

Table II.

No.	Diagnosis	Duration.	Age.	Results of Anaphyl. Tests.	Results.
1	Urticaria	5 months	38 years	All negative	
2	Urticaria; no lesions; history	2 weeks	29 years	Cow casein + Fish +	No improvement on corrected diet.
3	Urticaria	4 months	38 years	Cow casein +1 Oatmeal ± Egg ±	No improvement on corrected diet.
4	Urticaria	4 months; recurrent	30 years	Tests negative	
5	Urticaria; acute	3 days	33 years	Mutton +1 Beef +1 Egg +1	Diet corrected; no recurrence since correction of diet.
6	Urticaria	5 weeks	22 years	Cow casein ± Fish ± Pork ± Oatmeal ±	Disappeared from observation.
7	Urticaria	4 days	15 years	Cow casein +2 Fish ±	Itching stopped almost immediately after correction of diet.
8	Urticaria	5 years	31 years	Tomato +1 Oatmeal ± Clam ±	Diet corrected, but no influence on the itching.
9	Urticaria	1½ year	38 years	Cow casein ± Mutton +1	Slight influence on correction of diet.
10	Urticaria	4 days	19 years	Crab +1	Attack due to eating crabs; attack quickly subsided.

McBride and Schorer, in their article, Erythematous and Urticarial Eruptions Resulting From Food Sensitization, conclude that food may give rise to urticarial eruptions because it is not of the proper quantity; or because it is not properly chosen and prepared, or that certain proteins, no matter how simple they may be, prove harmful to the human structure. In our series of ten cases, eight showed positive anaphylactic food reactions, while two were entirely negative. In this series three were acute, and the remaining seven were chronic. In the acute cases the removal of the offending article caused a rapid subsidence of the eruption, and these tests serve as a guide to ward off further attacks.

In chronic urticarial skin conditions, we do not feel very hopeful. We do not believe that the presence of a positive anaphylactic food reaction holds out much hope for a cure in our patients. It is admitted that our series is small, and it is possible that a larger experience may cause a change in our present views.

PSORIASIS.

We studied eleven patients suffering with psoriasis:

Table III.

No.	Age.	Diagnosis.	Results of Anaphylactic Tests.	Results of Treatment.
1	56	Psoriasis; recurrent 15 years	Pork +1 Cow casein +1	No improvement
2	40	Psoriasis, with superimposed eczema	Cow casein ±	Lost from observation
3	30?	Psoriasis of 12 years' duration	Cow casein +2 Shell fish +1	Diet corrected; patient thinks she has improved
4	50	Psoriasis	Negative	
5	..	Psoriasis	Negative	
6	45	Psoriasis	Negative	
7	17	Psoriasis	Negative	
8	40	Psoriasis	Negative	
9	63	Psoriasis	Negative	
10	16	Psoriasis	Negative	
11	17	Psoriasis	Cow casein +2	

In this series, four gave positive reactions and seven were entirely negative. Only in one case was there some improvement in the eruption, following the installation of the corrected diet.

ACNE.

We studied thirteen patients suffering with acne vulgaris and three with acne rosacea. Out of this number there were five showing negative tests, while the remainder showed positive reactions. In none of our cases, although most of them were kept under prolonged observation, did any noticeable improvement follow the corrected diet.

CONCLUSIONS.

1. The anaphylactic food tests are of value in the etiological diagnosis and in the treatment of various diseases of the skin.

2. In our experience these reactions find their greatest value in eczema, where the development of a strong positive reaction holds out great hope for an improvement or cure in the skin condition, and in some instances an amelioration of the associated

gastrointestinal disorder by exclusion of the incriminated articles of food.

3. In chronic urticaria, acne vulgaris, and psoriasis the results of these tests are disappointing, inasmuch as the information secured from the cutaneous tests had not as a rule led to therapeutic success.

4. A very weak reaction obtained by the endermic injections, no matter what the food products may be, is not of convincing value, although it is advisable to correct the diet according to the findings. It is our practice where very weak reactions are obtained, to give diet a trial for a few weeks and if no improvement follows, the anaphylactic findings are disregarded.

Table IV.

No.	Age.	Diagnosis.	Duration.	Anaphylactic Food Tests.
1	17	Acne vulgaris	3 years	Cow casein ± Egg ±
2	23	Acne vulgaris	4 months	Cow casein +1 Wheat ±
3	21	Acne vulgaris	Several months	Negative
4	27	Acne vulgaris	Several months	Cow casein +1
5	30	Acne vulgaris with rosacea	4 years	Fish +1 Mutton ± Cow casein +3 Tomato ±
6	30	Acne vulgaris	9 years	Tomato +1 Pork ± Cow casein +2 Mutton ±
7	43	Acne rosacea	20 years	Shell fish +1
8	15	Acne vulgaris	2 months	Cow casein ±
9	..	Acne vulgaris		Cow casein +1 Tomato ±
10	..	Acne vulgaris		Cow casein +1
11	19	Acne vulgaris	2 years	Negative
12	..	Acne vulgaris		Negative
13	..	Acne rosacea	Several years	Cow casein +1 Clam +2 Pork ± Fish ±
14	18	Acne vulgaris	2 years	Negative
15	16	Acne vulgaris	2 years	Cow casein +1 Egg ± Wheat ±
16	14	Acne vulgaris	2 years	Negative

5. Given a case of chronic eczema, the anaphylactic food tests offer hopes for our patient so far as the possibility of rapid improvement or cure is concerned, and also with regard to conferring immunity against future attacks by the employment of prophylactic measures. It will not be necessary to starve our eczema patient unnecessarily and without rhyme or reason.

6. It is realized that a larger experience is needed fully to determine the value of this test.

We wish to express our thanks to those who have aided in this work and as always I desire to express my gratitude to my chief, Dr. Jay F. Schamberg, for allowing the use of the clinical material which has made this work possible.

4037 Girard Avenue.

Cysts of the Urachus.—John W. Means (*Annals of Surgery*, July, 1916) in discussing the treatment of cysts of the urachus, contrasts extirpation with incision, evacuation of the contents, and subsequent drainage. In only eight of Weiser's cases was extirpation done. This may have been due both to the great size of the cysts and the obscurity of the diagnosis. In the large cysts, it is doubtful if complete removal could be successfully practised, especially if the contents have become infected. The smaller cysts, however, do certainly permit such procedure, and care in attacking such cases will simplify the treatment.

PREDISPOSING FACTORS IN INFANTILE PARALYSIS.

By Max Talmey, M. D.,
New York,
Surgeon, Harlem Eye, Ear, and Throat Infirmary.

It would almost seem as if the prevalence in this country of infantile paralysis were a well deserved punishment for a grave sin we have committed, and are persisting in despite frightful warnings. The sin consists in not having heeded and still neglecting the teachings of the great epidemiologist and hygienist, my teacher, Pettenkofer. He established the principle that for every infectious disease predisposing factors are a condition *sine qua non*, thus putting the primary cause, i. e., the specific microorganism, into a place of minor importance. And yet our chief concern has always been and still is centred about the primary cause, so much so that we neglect entirely the search for predisposing factors and anxiously avoid even mentioning them, as may be shown by all discussions of the present scourge that threatens to decimate our infantile population. I do not hesitate therefore to make public the following reflections upon the burning question in our land, hoping that some good may be derived from the publication.

What are the predisposing factors in poliomyelitis? Evidently they are numerous, otherwise the plague would not be almost ubiquitous. The majority will probably remain unknown for a long time to come, but it would help a great deal in the combat against the scourge if we could ascertain and eliminate even one. I believe I have found one factor which is easily removable and not of minor importance. My belief is based upon the observation that formerly we had only sporadic cases of poliomyelitis, while now we are visited by regular epidemics in intervals more or less extended, the first epidemic having made its appearance seven to eight years ago, or three to five years after our factor had begun to be extensively applied. Three to five years would just be the appropriate time for the predisposition to develop from the factor. The coincidence of the first epidemic with the completion of this development is so striking that we must, *nolens volens*, investigate the factor, even though its efficacy in relation to poliomyelitis cannot be demonstrated, and even though we were convinced that the factor is not only not contributory to the disease, but may even aid in preventing it.

The factor I have in mind is tonsillectomy. The campaign to exterminate the tonsils started ten or twelve years ago, has been carried on relentlessly ever since, and has succeeded in making the well meaning general practitioner and even the lay public dread a piece of tonsillar tissue left back between the palatal arches after operation, as much as the cobra's venom.

There are two ways in which predisposition to poliomyelitis may develop from tonsillectomy, one of considerable and another of utmost importance. The first is the trauma, psychical and physical, caused by the operation. Weeks, nay months ahead, the child knows of the impending extermination of its tonsils and hears from playmates and schoolmates how awfully they have suffered long

before, during, and many, many days after the operation. These torture the child's mind incessantly from now on until the loss of consciousness in the narcosis, and all the sweet words of teachers, doctor, and parents have but the opposite effect, as I have shown in my treatise, *Psyche* (pp. 32, 141, 158), i. e., they aggravate the fear and anxiety for the simple reason that the child sees in them nothing but sugared lies. As one not unfamiliar with psychoses and their etiology (*loco citato,* pp. 93, 103, 113, 118, 153, 175), I consider this protracted fear a psychical trauma of the first order. Such a trauma will derange the vegetative functions of the nervous system no less than the psychical ones (*loco citato,* p. 1), and derangement of the vegetative functions of the nervous system is the most striking symptom of infantile paralysis.

The physical trauma attending tonsillectomy is just as great as, if not greater than the psychical one. There is, first, the protracted deep narcosis considered by the advocates of the operation to be a necessary requirement. The narcosis lasts seldom less than half an hour, very often almost double that time. There are, secondly, the mutilations of the palate, arches, and pharyngeal walls, which to a lesser extent, even the most experienced operator cannot always avoid. There is, thirdly, the prolonged healing period. I have recently examined a child three complete days after it had been operated on by an experienced pharyngologist, and found the whole pharynx up to the hard palate looking like one diphtheritic mass, and another child's pharynx, after the same time, looking like a battlefield in the present European war, though not white or gray. I told the operator the throats looked miserable and received the following answer accompanied by that well known sardonic smile: "Were the tonsils all out?" This was all that he was concerned about and is characteristic of the tonsillectomy fanatics, whose mental horizon seems to be no larger than the extent of the tonsil or of the tympanic membrane. In another case, still under my observation, I found the pharynx, four weeks after operation in a prominent hospital, covered with almost fresh sores, both ears filled with an abundant mucopurulent discharge, and fever. That such trauma should pass off without leaving the nervous system in a state of permanently weakened resistance toward all kinds of injurious influences, is hardly to be believed.

Such trauma, psychical as well as physical, never took place in the era of tonsillotomy. There was no prodromal fear, no protracted narcosis, the latter not being continued any further than the very first stage and often omitted entirely, no mutilation of the pharynx, and no prolonged healing period. The whole operation rarely lasted longer than a second or two for each tonsil and a few seconds for the adenoid vegetations and some parts of them that may have remained hanging in the throat, altogether about one minute. Frequently I applied the following method. A mother brought her girl to me from Boston to be examined whether the child had enlarged tonsils. I took the tonsillotome, told the child it was a tongue depressor, and hardly had the child opened her mouth when the pretended tongue depressor made a thrust at the tonsil, grabbed it quickly, and left the mouth with the greatest part of the tonsil hanging on its grasping prongs. The second tonsil was removed no less expeditiously by telling the child to open her mouth at once, as otherwise she would bleed to death. The mother is my sister, the child my niece, an exceptionally beautiful girl of twelve years; both are living hale and hearty in Medford, Mass. The same method I have applied with a niece of the late Doctor Schaie, and last but not least, with my own dear child, a girl of eight years and not less beautiful than her cousin. The prodromal fear is certainly excluded in this method.

The second way for the predisposition to develop from tonsillectomy, which I have stated to be of utmost importance, is the elimination from the system of a valuable protective substance the nature of which is yet unknown. This substance may either be directly contained in the tonsils or else produced from the blood or other organs by the mere presence in the body of the tonsils. The latter may act in the manner of ferments, so that even minute quantities of their tissue suffice to keep up the continued production of this valuable protective substance. The latter mode of their action is the more probable one. In this regard the tonsils may have the same relation to poliomyelitis as the thyroid gland has to acromegaly, cretinism, and myxedema, for which three diseases the diseased thyroid gland probably forms the common point of contact, as I have expressed it in my dissertation entitled, Ein Fall von Zwergwuchs mit Beziehungen zu Akromegalie, Cretinismus und Myxoedem.

To determine whether or not my views of tonsillectomy furnishing a predisposing factor of poliomyelitis are correct, the following three questions should be put, in an official blank, to every physician attending a case of infantile paralysis:

1. Has an operation been performed on the tonsils? How long ago?

2. Was the operation tonsillotomy or tonsillectomy?

3. Are there any mutilations of the pharyngeal walls, and what are their nature and extent?

I have suggested these questions to the health board and have received the assurance that they will be studied by a "corps of special physicians." I am sure it is composed of the best clinicians aided by only one unbiased and competent nasopharyngologist, who, on the one hand, has never participated in the campaign to exterminate the tonsils, and, on the other hand, does not consider a slight nasal catarrh or a small piece of adenoid tissue in the pharyngeal roof or of tonsillar tissue in the fauces as much a menace to the human race as 0.25 diopter of uncorrected astigmatism (see my article, Reflections on Ophthalmological Successes, New York Medical Journal, December 2, 1905).

After having gathered all the statistical data they will have to be carefully sifted. This is a very difficult task for which the best statisticians will be needed (see *Psyche*, p. 104). It would lead us too far to go into details in this respect. If after taking consideration of all possible errors five per cent. remained in which tonsillectomy is the only demonstrable predisposing factor, the correctness of my views is proved.

I would further suggest to make experiments with all kinds of extracts and other products of the tonsils in order to find their active principle and to treat afterward with it cases of poliomyelitis, including in the treatment all children of a family, even those not yet afflicted.

In countries affected much by poliomyelitis and little or not at all by tonsillectomy, it devolves upon the authorities, clinicians, and laboratory workers to search for other predisposing factors which may be even more potent than tonsillectomy.

It is possible that statistical as well as experimental data may prove my views on tonsillectomy to be entirely fallacious and even the operation to be beneficial, though no child who has had the ill luck to be tortured by one surgeon, two assistants, and one or two nurses at the same time will ever admit the benefit. Nevertheless not one iota would be detracted from the worth of this publication. For its gist does not consist in the criticism of tonsillectomy, which is perhaps unjustified, but exclusively in having called attention to the fact that in all infectious diseases, not only in poliomyelitis, our efforts are bent in a wrong direction. It would be a great saving of energy, less expensive in the end, and incomparably more productive of practical good results to search for predisposing factors rather than hunt after specific microorganisms.

Before concluding, I wish to quote a remark of an intimate friend of mine. I consider him to be one of our best tonsillectomists, for more than once I have seen him perform the operation in the least possible time, with the least possible hemorrhage, and with the least possible injury to the pharyngeal walls. When I told him that I had proposed to the commissioner of health to investigate three questions he not only almost guessed them, but even added: "I am well aware that some morning we may wake up and find that with our tonsillectomies we have done more harm than good. For we do not know yet the functions of the tonsils." The contrast between so broad-minded a statement and the above quoted retort, "Were the tonsils all out?" is both striking and refreshing.

I will brave the storm of criticism that may break out over this article with the following quotation from Horace:

Si fractus illabatur orbis,
Impavidum ferient ruinæ.

51 West 126th Street.

EARLY PULMONARY TUBERCULOSIS.*

The Signs and Symptoms.

By Robert Abrahams, M. D.,
New York,
Adjunct Professor of Medicine and Adjunct Physician, Post-Graduate Medical School and Hospital; Consulting Physician, Manhattan State Hospital.

The amount of time and attention devoted to the study of pulmonary tuberculosis in every land and in every clime, overwhelmingly attests the great and everlasting interest and importance of the disease. First and foremost in this widespread human affliction is its early recognition. Upon it depend effective measures of prevention and successful methods of treatment. The awakening of the profession to this fundamental point in tuberculosis has resulted in perfection of methods in diagnosis, reduced mortality, prolongation of life and usefulness, limiting, arresting, and curing the affection. This assertion is not a flight of the imagination, for who has not noticed the scarcity of patients in the third stage of the disease?

Few problems in medical diagnosis are less difficult of solution than incipient pulmonary tuberculosis, provided that we go about it in an orderly, methodical way, instead of a slipshod, rambling, and haphazard fashion. As in all lesions, signs and symptoms enter into the scheme of this lesion. Symptoms stand in relation to signs as smoke stands to fire. There is no smoke without fire, and there are no symptoms without signs.

In examining a patient for suspected tuberculosis of the lungs, it is well to apply ourselves to the pulse and heart first. There is not an organ in the body which responds to tuberculous infection of the lungs more quickly than the heart. In health the aortic second sound is louder than the pulmonic second sound. Conditions are immediately reversed in the event of tuberculous implantation. In the very incipiency of the disease, the second pulmonic becomes loud and accentuated. We may regard it as pathognomic, considering that it is always present. The only other conditions which give rise to this sign are mitral insufficiency and mitral stenosis. Excluding those, it is safe to assume that an apex is in trouble, and he who seeks shall find: this is a good motto in physical diagnosis. Next is the pulse. No matter how young the infection is, the pulse will be found accelerated, sometimes more and sometimes less, but, barring a case here and there, the rate is never normal. In some, the increased rate is more noticeable in the afternoon, in some, it is more marked in the evening; in some at rest and in some after slight exertion; at one time or another, the pulse phenomenon is characteristically constant. There is another feature about the pulse which points to early tuberculosis, and that is its total extinction when palpated while the arm is held in the upright position. In a few cases, instead of complete disappearance of the pulse, there is marked diminution, but only in a few cases. This phenomenon is observed in one arm only, and the indication is that the apex corresponding to that arm is the seat of the infiltration. This sign is present in incipient tuberculosis; an advanced lesion does not show it. It may also be added that this peculiarity of the pulse is found in eighty per cent. of cases.

Having learned this much about the lungs from the heart and pulse, the next step is inspection of the chest. The inspection of the chest anteriorly in early tuberculosis is more important than the inspection of the back. Normally the right apex expands more fully than the left apex. If the right apex expands as much as or less than the left apex, then suspicion should rest on the right apex. While this is not the most important sign of early tuberculosis, yet when it is present it is helpful. Retraction of the infraclavicular and supraclavicular spaces is not symptomatic of incipient tuberculosis. Retractions indicate advanced conditions. An in-

*Read, by invitation, before the Williamsburgh Medical Society, February, 1916.

teresting point about the retraction of those upper and lower spaces is that unilateral retraction points more strongly to tuberculous involvement than bilateral, for the reason that bilateral incipient tuberculosis is comparatively rare.

Sagging of the side of the chest corresponding to the site of the lesion is considered by Pottinger to be indicative of early tuberculosis. This may be correct, but its absence does not exclude the disease; besides, this condition is found to exist in perfectly healthy chests. Protruding ears; pinched face; glistening eyes; winged scapulæ; irregular pupils and a red line on the upper gum—these do not belong to early tuberculosis of the lungs. Some of them belong to the romance of tuberculosis, even in the advanced stages.

The next and third step in the examination is palpation of the chest. Again let me point out a normal difference between the two apices. As we stand behind the patient and place the finger tips over the apices, the patient is told to repeat one, two, three, or ninety-nine. The articulation will produce a vibration known as fremitus, which will be better perceived in the right apex than in the left. This normal difference points a lesson in diagnosis, namely, if the vocal fremitus in the left apex is as strong as it is in the right apex, assuming that the right apex is normal, it may reasonably be inferred that the left apex is slightly infiltrated. Unfortunately there is no standard of comparison for the right apex except experience.

The fourth step in the examination is percussion. Pages upon pages are written and published on methods, manner, and technic of percussion. Some say strike hard; some say hit gently; others advise to do a tapping. tapping, gently rapping, like the raven in Poe's poem. Amid multitude of advices there is no lack of confusion, but a happy medium is always the best, the safest, and the sanest, as in all things.

Just a few words about the art end of percussion; what I shall say may sound elementary, but the more elementary and the simpler the subject, the better it is understood. Employ two fingers for a hammer and one for a plexímeter; percuss from the wrist instead of the elbow; let the stroke be light, easy, and uniform. Use the left thumb as a plexímeter for the right apex and the left ring finger for the left apex. While the plexímeter is on the chest and in position, keep the other fingers of the same hand away from the chest, in order that they may not carry off some of the percussion sound that is intended for the ear. It is best to place the plexímeter on the intercostal spaces, although for careful percussion, the ribs, like the clavicles, should be percussed. The whole thorax should be percussed, from apex to lower border, before any part is auscultated. Wherever a change is noted, it should be marked with a lead pencil.

Of the four attributes of a percussion sound, the two most important are duration and pitch. The most important of the two is duration. Every one should mentally measure the duration of the sound from the time of its production to the time of its disappearance. Long duration means normal lung, short duration means slight infiltration, still shorter duration means more infiltration, and no duration signifies complete consolidation.

There is one cardinal principle in percussion of the chest, and because it is cardinal it is invariably honored in the breach. *Percuss corresponding areas,* not making a hit in the left apex, then a stroke at the third rib, and winding up the performance with a blow at the solar plexus, for a grand finish.

But even if we are complete masters of the fine art of percussion, we still have to learn an important lesson without which our art and skill will go for naught. This lesson refers to a knowledge of the physiological conditions of the lungs as pertaining to percussion sounds, in order properly and accurately to assess the value of tones and sounds under pathological circumstances.

This introduces a very interesting subject, and as I am not writing a textbook on physical diagnosis, and as my sole desire is to elucidate the subject under discussion, I shall take up for consideration sounds which are of essential value in early diagnosis of early tuberculosis. The important percussion notes are: Vesicular, dull, and flat. I wish to mention another percussion note which I have described[1] and many times demonstrated. The name of that note is *dull-flat.* The value of it will become apparent as the discussion develops.

To know the pathological we must be familiar with the physiological, therefore it is opportune to inquire at what areas of the chest are the notes mentioned normal? The answer is as follows: Vesicular resonance is normal in the left apex, below the left clavicle, below the second right interspace, in the axillary spaces, and over the lower lobes.

Dullness is normal in the right apex; in the second right interspace, especially the outer half of that space; intrascapular spaces; between the seventh cervical and fourth or fifth dorsal vertebræ; and over the deep area of the heart.

Flatness is normal over the scapulæ and the superficial area of the heart.

If there is any deviation from the physiological standard, we must suspect tuberculous trouble and investigate further. The normal difference in the percussion sound between the two apices should never be forgotten. Its lesson in incipient tuberculosis is obvious, namely, should the left apex be found to be as dull as the right apex is normally, the left apex may be adjudged guilty of early infection. Now in case the right apex becomes infiltrated, what change does its normal dullness undergo to indicate the trouble? Considering that tuberculous infiltration is of slow growth, barring acute conditions with which this paper is not concerned, we need not expect to find one day dullness and the next day flatness. The change therefore consists in a note which is duller than dull but not as flat as flat should be. The sound is between and betwixt, and for the sake of clearness and comprehension, I named it dull-flat. This name has an honored parallel in a respiratory murmur which was named by that great American physician, Austin Flint, "bronchovesicular," a murmur which is neither bronchial nor vesicular, but shares the qualities of both. Vesiculotympanitic resonance is also an Austin Flint idea, and one which may serve as a parallel and precedent.

[1] See *Archives of Diagnosis,* July, 1910.

If this name is accepted, it follows that a dull-flat note obtained over the right apex indicates incipiency, and that the incipient stage wrought that change in the normal dullness. Another practical lesson that is taught by this dull-flat sound is, that whereas if that sound is present at the right apex it indicates incipiency, if the same sound is elicited from percussing the left apex, the indication is that the lesion in the left apex is further advanced, for that would mean a double change for the normal vesicular resonance of the left apex.

The dull-flat note is a pathological sound. It is found nowhere on the normal chest. If anybody should be in doubt as to whether he is dealing with a dull-flat note or ordinary physiological dullness, the patient is asked to take a deep breath and hold it. Under this influence, if the apex is normal, its expansion is normal and the increased air in it will change the sound from dull to vesicular; on the other hand, if the sound is that which I have dubbed dull-flat, no change will be perceptible. This is the test, the crucial test.

Stress is laid on the careful examination of the apices, because they are the victims four hundred and ninety-nine times out of five hundred. This is Osler's dictum. What is the value of percussion in the early diagnosis of pulmonary tuberculosis? Any physician who is skilled in the art of percussion can with reasonable certainty diagnose incipient tuberculosis of either apex by percussion alone.

The fifth step in the examination of the patient is by means of auscultation. This aid to physical diagnosis is practised successfully by many more physicians than is percussion. There is less of the personal equation about it and less confusion about methods. This is probably the key to its popularity and credited superiority to percussion.

Before commenting on the significance of auscultation in the diagnosis of early tuberculosis, mention may profitably be made of a few vital points. The three cardinal respiratory sounds are: Vesicular or pulmonary; bronchovesicular, and bronchial or tubular. It is well to study these breath sounds in their relation to healthy conditions of the lungs in order to comprehend their meaning in disease.

The vesicular murmur is found in the left apex and below the left clavicle down to the base of the heart; in the axillary regions; over the lower lobes; and below the right clavicle.

Bronchovesicular breathing is normally heard over the right apex; in the second intercostal spaces close to the sternum; and in the interscapular spaces. Practically, bronchovesicular breathing follows the lines of normal dullness.

The place for bronchial breathing in health is the trachea and larynx. The essential features of these types of breath sounds are: Vesicular breathing is characterized by a long and full inspiration and a short expiration, expressed numerically, as three to one. Bronchovesicular breathing is characterized by inspiration and expiration being of the same duration and higher pitch. Bronchial or tubular breathing is recognized by its long expiration and very high pitch. It may be added that the expiratory sound both in bronchovesicular and tubular breathing is of higher pitch than the inspiratory sound.

In early tuberculosis, the following changes take place in the breath sounds: Vesicular breathing becomes bronchovesicular; bronchovesicular breathing changes to the extent that the expiratory sound becomes longer than the inspiratory sound; tubular breathing has no room in the diagnosis of incipient pulmonary tuberculosis.

In the application of this knowledge, it is well to take up concrete examples, as follows: If the right apex is the seat of an early infiltration, the change that its normal bronchovesicular breathing undergoes is that the expiratory sound grows longer than the inspiratory sound. In case the left apex is the seat of an early tuberculous infection, its normal vesicular murmur changes into bronchovesicular. Incidentally it is to be noted and emphasized, that a prolonged expiratory sound in the right apex denotes incipiency, while a prolonged expiratory sound in the left apex indicates an advanced process. The reasons are obvious. These points are of very great value. Diminished breathing as a result of early tuberculosis, in my experience, is a rare physical phenomenon.

The spoken voice and the whispered sound are muffled and indistinct over areas of vesicular breathing and very distinct over areas of bronchovesicular breathing. Thus both are muffled and indistinct over the left apex, and clear and well defined over the right apex.

In early tuberculosis of the left apex, we need only to compare the voice and the whispered sound in that apex to the voice and the whispered sound of the normal right apex to be absolutely sure of the diagnosis. The increased whispered sound is pathognomonic. The changes in the voice and the whisper in the right apex, in early infection, are hard to measure, as they have no standard of comparison; experience and "acromion auscultation" will lead to a correct diagnosis.

As a guide to a diagnosis of early tuberculosis of the apices, I will draw the normal differences of the apices in parallel lines:

Right apex.	*Left apex.*
Tactile fremitus present.	Tactile frenutus absent.
Voice present and distinct.	Voice absent or indistinct.
Dullness on percussion.	Vesicular resonance.
Bronchovesicular breathing.	Vesicular breathing.
Whispered sound distinct.	Whispered sound indistinct.

The value of auscultation at the acromion processes as an aid to apical tuberculosis need not be reasserted. It is a method worth practising and adopting in the daily work of the examination of patients who are suspected of tuberculosis of the lungs. I have described the method in two papers (*Archives of Diagnosis,* April, 1913, and April, 1915).

Thus far the paper has dealt with *signs*. I shall now very briefly take up *symptoms*.

Years of experience with pthisical patients, compel me to the conclusion, first, that many patients with early pulmonary tuberculosis show no symptoms whatsoever; second, those who show symptoms are victims of systemic as well as tuberculous infection; third, that if symptoms are out of proportion to signs, the systemic infection is the predominating element in the patient's misery; fourth, some patients show symptoms resembling those of tubercu-

losis who eventually die of cirrhosis of the liver or cancer of the stomach that gave neither signs nor symptoms during life.

Persistent hoarseness is a symptom of early tuberculosis. It is present only in a few cases in the beginning of the disease. Cough is not a common symptom. Many patients with unmistakable signs show no cough at all. When cough is present, it is dry or attended with scanty mucous expectoration. Dry cough results from pleurisy, localized over the lung lesion, in which case it is a reflex cough; or the tubercles alone acting as irritant foreign bodies, produce the cough; or tubercles are present in the mucous membrane, causing a mild degree of inflammation attended by mucous secretion and cough, or there is an ordinary bronchitis, local or general, which is responsible for the cough. In the incipient stage, the cough is bothersome mostly at night, interrupting sleep, or it troubles the patient in the morning. Cough of that character should always be looked upon with suspicion and prompt a careful physical examination of the chest. As the nasopharyngeal tract and heart are frequently responsible for persistent and annoying cough, these factors should be removed from consideration before blaming the lungs.

Dyspnea is hardly ever present in early tuberculosis, but when an otherwise healthy person complains of getting out of breath at the slightest exertion, it is well to think of possible incipient infiltration.

Slight hemoptysis is a common but not constant symptom in the incipient condition. Raising of blood in the very early stage of tuberculosis results from congestion or very slight erosion of the mucous membrane of the bronchi. Inasmuch as hemoptysis may be the very first indication of tuberculosis, which brings the patient to the doctor, it is well to remember that raising of blood may result from other conditions, for example excessive bodily exertion; excessive mental excitement; spongy gums; hypertrophied tonsils; chronic pharyngitis; acute or chronic laryngitis; mitral disease; vicarious menstruation; anemia; chronic bronchitis; angioneurotic edema; arteriosclerosis; small aneurysms; or, as the late Doctor Delafield used to say, "hemorrhages may occur in patients who seem to have nothing the matter with them."

Fever is not a frequent symptom in incipient tuberculosis. When fever appears steadily and with a tendency to rise, the disease is no longer incipient. If fever is present a part of the day and is constant in coming, and if signs do not warrant a diagnosis of first stage tuberculosis, the fever may be explained by the assumption of the presence of a severe systemic infection added to the tuberculous toxin. The proper appraisal of fever in early tuberculosis can be made only when all other conditions which give rise to fever have been intelligently and painstakingly excluded.

While on the subject of fever and rise of temperature in early tuberculosis of the lungs, I shall take the liberty to repeat the value of surface or local temperature. I cull a brief abstract from my own paper on the subject which was printed in the NEW YORK MEDICAL JOURNAL for January 8, 1910. "Away back in the sixties, Peter made a careful study of local temperatures in phthisis and other diseases. He found 'that the temperature of the affected side was always from three tenths to one degree centigrade higher than on the other.' (Supplement to von Ziemsen's *Cyclopædia of Medicine.*) Availing myself of this observation, I applied it to the study of incipient pulmonary tuberculosis. Peter apparently employed his method in well established cases. Most of my tests have been made in apical infections, and were made after the diagnosis of incipient tuberculosis was established by physical examination. The difference in temperature between the diseased apex and the healthy one was obtained regardless of the time of the day, although it was most marked between the hours of four and six p. m. The smallest difference that was ever registered was 0.6 and the highest two degrees Fahrenheit."

Increased experience confirms my first results with this sign in early tuberculosis. Success can be expected in eighty per cent. of cases. This local temperature in incipient tuberculosis is perhaps best explained by the fact that the affected lung is in a state of congestion or hyperemia; an increase of blood in a circumscribed area raises the temperature of that area. This must be the right explanation, because in advanced or ulcerative stages, surface fever is but rarely present.

Loss of flesh and strength in the incipient stage is, in my experience, uncommon. Patients in that stage may have a capricious appetite, a feeling of fatigue, but no distinct or appreciable loss in weight. When the weight of the patient is beginning to suffer, then either the infection has passed the threshold of incipiency, or the incipient stage is aggravated by systemic infection, or the patient was unduly frightened about the disease by an indiscreet doctor or somebody else; perhaps the ubiquitous social worker or the policing nurse of the health department.

Rales, moist, dry, or musical, are highly suggestive if not absolutely pathognomonic of early tuberculosis in an apex. They are of little or no value around the borders of the lower lobes. This statement is especially true with reference to moist rales. Almost everybody has mucous rales in and around the borders of the lower lobes: this is probably due to the neglect of deep breathing. After examining literally hundreds of patients affected with incipient pulmonary tuberculosis, I have come to the conclusion that a great majority of early cases have, at one time or another, or at one examination or another, some kind of rales. In most instances it is a matter of perseverance on the part of the examiner. There are rales, however, which may with perfect propriety be called dormant. Their delicacy and fragility prevent them from being heard with the ordinary method of auscultation. To bring them to life we may employ one of three methods, or all three: 1, Auscultate the apex while the patient coughs and breathes; 2, the patient is given five grains of potassium iodide three times a day for two or three days; 3, place the stethoscope over the acromial end of the clavicle. This procedure will elicit rales when nothing else will. (See *Archives of Diagnosis,* April, 1913, and April, 1915.)

The question as to which rales are oftenest heard over an incipiently infected apex must be left to the

specialist on statistics. The clinical fact is sufficiently conclusive, that rales of any description, moist, dry, or musical, wakeful or dormant, as it were, spell tuberculosis in the great majority of instances. The insignificant exception is found in time of grippe, when an individual affected with that annoying disease involving the upper air passages, may show a few stray moist rales at the very tip of one or both apices. These rales may remain for some time, much to the confusion of the examining physician. When we observe the total absence of other physical signs, however, the grippe rales become only of academic interest. I noticed that grippe rales quickly disappeared by changing climate even if the change lasts no longer than a few days; while rales indicative of tuberculosis remain and are slow to disappear under the best climate and long stay. An elusive moist rale is heard once in a while over an apex in patients who have serious obstruction in the nasopharyngeal passages, but it permanently disappears after the trouble in those air passages is removed.

What is the requisite number of signs to justify a diagnosis of early tuberculosis? The answer depends entirely on the physician and his skill and experience. One skilled in percussion, for example, may detect a change in an apical resonance sufficient to justify a diagnosis of incipiency. Or, one possessing a correct knowledge of the acoustics of the apices or other parts of the lungs, but particularly of the apices, may safely draw inferences regarding diagnosis from one sign only. The majority of observers must elicit at least *two* signs for a justifiable diagnosis. It makes little difference which two, the point is that for the nonexpert there is safety in numbers. Sometimes the presence of a sign and a symptom will and does furnish the necessary data for a correct diagnosis of early tuberculosis.

A careful study of the foregoing statements and facts compel me to conclude that the diagnosis of early tuberculosis of the lungs is not beset with insurmountable difficulties; that it is but a question of correct knowledge of the physiological conditions of the lungs, first and foremost, and an enlightened interpretation of the pathological findings at the time of the examination; signs to be considered supreme, symptoms as handmaids to signs. Finally, if it is not heresy, and as an added assertion to all that has gone before, the microscope and the x ray are more ornamental than useful in this stage of tuberculosis, and frequently delay treatment by their negative results.

257 West Eighty-eighth Street.

Limited Value of Bromides in the Treatment of Epilepsy.—William T. Shanahan (*Medical Review of Reviews*, July, 1916) tells how greatly the use of bromides has decreased at the Craig Colony for Epileptics, and points out that with this material reduction in the use of the drug there has not been an increase in the average number of seizures, but rather the contrary. His object in the paper is to try to impress the fact that the bromides in the treatment of epilepsy have a much more restricted application than is ordinarily considered to be the case.

URINARY TOXEMIA.*

By Willard H. Kinney, M. D.,
Philadelphia,
Demonstrator Genitourinary Diseases, Jefferson Medical College; Chief Clinical Assistant, Outpatient Genitourinary Department, Jefferson Hospital.

Urinary toxemia is a chronic autointoxication due to some disturbance of, or interference with renal function (1), ranging from a mild toxic condition to the more grave or uremic syndromes; the onset may be sudden and acute, or it may steal upon us insidiously.

The incidence depends largely upon the careful clinical research as well as definite determination of renal function; keeping in mind such relative factors as acute or chronic nephritis, the various albuminurias, scleroses, myocardial insufficiency, polycystic kidneys, obstruction in the lower genitourinary tract, cystitis, pyelitis, unilateral or bilateral hydronephrosis, pyonephrosis, pyelonephritis, the hypernephromata, renal tuberculosis, ureteral or kidney stone, and numerous allied conditions which call for differential diagnosis (2). The causes of urinary toxemia are practically reduced to one condition, viz., inability of the renal epithelium to perform its function. The acute forms occur first as an acute postoperative renal congestion, and second as an acute reflex renal congestion.

The chronic urinary toxemias may arise from chronic obstruction along the genitourinary tract, or chronic interstitial nephritis. The symptoms are summed up, whether of the acute or chronic type, as those coming under the symptomatology of uremia, varying in degree from slight febrile and gastrointestinal disturbances to the profound slumbers of uremic coma. Hartman (3) has isolated from the urine a light yellow oil possessing the empirical formula C_6H_8O and giving the reaction of a cyclic ketone. This oil which he calls "urinod" has the odor described as urinous and apparently is the source of the odor of urine. It exists in conjugated form in normal urine, and when isolated in the free state is intensely toxic. Hartman tested the effects of extremely minute doses on himself, and observed symptoms of intense nausea, occipital headache, loss of appetite, heaviness of the stomach after eating, drowsiness, and continual malaise; on other occasions he noted irritability, restlessness, insomnia, inability to concentrate the attention, chilliness, and a desire for frequent micturition. He suggests that since the odor is due to urinod, the presence of a urinous odor on the breath, skin, and in the blood of uremic patients, may be taken as evidence of urinod retention and, further, that since symptoms of urinod poisoning resemble in many respects certain of the nervous manifestations of uremia, it is possible that the retention of this material may account, in part at least, for these symptoms. Foster (4) has reported the isolation of a highly toxic crystalloid not found in normal blood, which upon injection excites many of the symptoms of uremia.

Disturbance of the gastrointestinal tract is often an early indication of renal insufficiency, e. g., obstinate constipation, slight nausea with occasional vomiting, and sometimes profuse diarrhea occurs.

*Read before the Philadelphia Genitourinary Society, Branch of American Urological Association, January 24, 1916.

Headache, constant in type, is always suggestive of toxemic conditions of the renal organs. Abercrombie (5) has published an interesting report on acute renal disease occurring among the troops in France; he gives a series of ninety-five cases in which headache was the most constant symptom. The onset was sudden in some of the cases, and in others the symptoms were slight and became progressively worse in a few days; in addition to headache the majority of the patients suffered from vomiting and nocturnal paroxysms of dyspnea; the tongue was usually furred and dry; convulsions occurred in three patients. An interesting fact is that none of the patients succumbed. In only a few cases could Abercrombie regard these conditions as exacerbations of chronic nephritis. From the symptoms at the onset and the irregular incidence, the cause was at first thought to be an anomalous form of influenza, but although organisms resembling Bacillus influenzæ were found in the sputum of patients having bronchitis, they were not recovered from the urine; cultures of the urine and blood remained sterile. Upon reviewing these facts Abercrombie has concluded that the disease is an infection by a definite organism the nature of which has not as yet been determined. Before making a diagnosis or prognosis in any case, certain questions must be considered: 1. What pathological condition underlies the clinical picture? 2. Is the condition restricted to the kidney, or is any other system (cardiovascular) involved? 3. What is the functional capacity of the kidney; is it permanent or temporary and subject to change? 4. Is the condition amenable to treatment? Functional studies reveal only the excretory capacity of the kidney, and alone do not determine the diagnosis. It is possible that a series of ten or twelve different tests may add little or nothing to our knowledge of the condition, after careful clinical study; whereas after an equally careful clinical study, one test verified may change all our ideas concerning the diagnosis, prognosis, and treatment. Clinical or functional studies alone are inadequate from the standpoint of prognosis. A perfectly normal urine may be excreted by a congenitally deficient kidney. There are on record numerous instances of death following nephrectomy, owing to the presence of this unrecognized deficiency of the kidney which has been left to do all the work. A prognosis may be safely made concerning the ability of any kidney to carry on renal function alone, even when catheterization of the ureter is impossible, and when the urine has been collected through an infected bladder, provided a catheter can be inserted into the other ureter. Extremely low functional capacity in chronic nephritis means death as a rule, but in obstruction of the lower genitourinary tract with urinary retention and back pressure, the injury may be mostly functional, so that after appropriate treatment a fair or good capacity may be reestablished.

In passive renal congestion the phthalein output is usually reduced, and in cases of marked cardiac decompensation it may be a mere trace, but rapidly rises upon improvement of the circulation. In degenerative nephritis the output of phthalein is variable; several instances have been cited in which there were marked albuminuria, casts, and some disturbance of chloride elimination, but with normal phthalein excretion or even an output above normal. In acute glomerulonephritis the phthalein output may be only moderately reduced or its elimination may be zero.

In the uremic conditions the creatinin retention in the blood is most marked; the valuable results of this test are in relation to prognosis. Myers and Lough (11) report a series of thirty cases in which there was retained over five mgm. of creatinin to the 100 c. c. urine; the termination was invariably fatal within two months. The estimation of the creatinin in the blood in nephritis, as stated previously, is valuable not only in relation to prognosis, but to diagnosis as well. In renal involvement the creatinin rises above 2.5 mgm. to the 100 c. c. almost without exception. Creatinin value from 2.5 to three mgm. may be viewed with suspicion, from three to five mgm. as decidedly unfavorable, and over five mgm. as indicating early fatal termination. In cases where the nonprotein, nitrogen, and phthalein tests have been carried out simultaneously there has been a most excellent agreement between the two tests. The difference, however, is that the amount of phthalein excreted shows the renal function at the moment, while the nonprotein and urea nitrogen are rather a measure between the amount of waste nitrogen produced in metabolism and that eliminated by the kidney. In early stages the phthalein test probably yields more valuable information; but after a decided retention has occurred the nonprotein and urea nitrogen of the blood furnish a more accurate index of the changes in the patient's condition.

Tileston and Comfort (6) have reported a case of acute nephritis with zero phthalein, which ended in recovery. Freeman (7) also has reported the case of a child with only three per cent. elimination, with complete recovery. In the chronic glomerulonephritis in which there are albumin and casts, and the blood pressure is elevated, the renal function tests are normal; the phthalein test is no exception to this rule. As the case progresses, however, elimination gradually diminishes. In the series reported by Thayer and Snowden (8) the minimal point was reached anywhere from one day to a month before death. Monakow (9) has concluded that marked diminution in phthalein is an indication of severe loss of renal function; on the other hand, a normal phthalein excretion does not exclude renal disease. Changes upward and downward in the function test have prognostic value. In severe disorder, such as coma or convulsions, a normal phthalein output usually excludes true uremia, whereas a greatly reduced phthalein renders it extremely probable that the condition is of renal origin. Neubauer (10) has suggested the administration of creatinin as a function test, since it is the one normal urinary constituent which is entirely endogenous, and the rate of excretion of added creatinin may be readily followed.

Ambard (12) asserts that the relation between the concentration of urea in blood and that eliminated in urine furnishes a more reliable index of the functional condition of the kidneys than the content of urea in blood alone; these contentions have been supported by more recent experiments of Mar-

shall and Davis (13) and McLean and Selling (14). A study of postoperative renal function has been made by Miller and Cabot (15); they found the phthalein output usually diminished, especially after laparotomy and operations for cancer. Generally speaking, the diminution is proportionate to the amount of ether used and the length of operation. Shock decreases the elimination of phthalein, while postoperative albuminuria is not in proportion to the phthalein reduction.

Postoperative renal infection is more frequent than was formerly believed (16), owing first to the fact that in many cases it is overlooked on account of the mild character of infection; second, vesical irritability occurring after operation may be an important precursory sign of renal infection; third, a study of the urine will probably show the type of disease present. We should avoid nephrectomy if possible by a careful study of the pathological condition at time of operation.

The amount of permanent damage done by an attack of acute nephritis in childhood has been studied by Ernberg (17), who succeeded in locating and examining forty out of 106 adults who had had an acute nephritis before the age of fifteen years, mostly in connection with an acute infection, and found normal urine in all; further, he examined sixteen out of fifty adults whose acute nephritis had occurred between the ages of fifteen and thirty years, and found all normal except in four cases; two of these gave evidence of nephritis of recent origin, and the other two, whose original attacks had been subacute rather than acute, showed albuminuria. If these figures present a true picture, it is certain that we have been too pessimistic about the prognosis of nephritis in childhood. In conjunction with the foregoing citation I take the liberty of reporting a case seen in Professor Loux's service at Jefferson Hospital.

Case. A boy of twelve years was admitted for operation upon an undescended testicle; four years before, he had had a severe attack of measles, and two weeks before admission to the hospital had been treated by his family physician for grippe; temperature on admission was 100° F., which subsided to normal. Operation was regarded as urgent on account of severe pain in the undescended testis and canal, suggesting a possibly malignant condition. Oliguria was present, patient not voiding more than 450 c. c. in twenty-four hours. Owing to this decreased output and the presence of albumin and a few hyalogranular casts in the urine, it was decided to postpone operation. On the third day, the patient became more or less stuperous and suddenly manifested a clonic convulsion, first attacking the left arm; condition became progressively worse; convulsions increased in frequency and length of attacks. On the fifth day, the patient succumbed, death being due to respiratory failure; the cardiac impulse was discernible four minutes after respiration ceased. The autopsy showed an acute parenchymatous nephritis and a few calcareous plaques on the mitral valves. The histological diagnosis was acute degenerative nephritis, edema and fibrosis of mesenteric lymph nodes, and persistent thymus.

This case is interesting from the standpoint of the renal condition, whether the acute exacerbation of a chronic nephritis resulted from his infection four years previously, or from the recent attack of influenza.

TREATMENT.

In summarizing the treatment of urinary toxemia, success depends on one factor—elimination. The three avenues through which we hope to accomplish this end are the kidneys, bowel, and skin. An initial dose of calomel, five to ten grains, followed by a saline, will produce excellent purging; while calomel also acts as a diuretic, further elimination of toxins from the intestinal tract can be brought about by high colonic irrigations of salt solution. Hypodermoclysis and intravenous saline transfusion are indicated in certain cases. Diaphoresis is best accomplished by the dry hot pack, preceded by some cold acidulated drink and the application of an ice cap to the head. In robust patients pilocarpine can be administered hypodermically to enhance diaphoresis. Activity of the skin can be maintained by systematic alcohol rubbings; for the dry, furred tongue, nitroglycerin grain 1/100, every three hours, seems to be the best drug to restore moisture. This also mollifies the pulse tension; digitalis, owing to its irregular standardization and strength, as well as its unstable properties, cannot be relied upon, although where it is possible to obtain a fresh preparation of some of the alkaloids, it acts admirably as a cardiorenal stimulant. As a substitute for the above mentioned drug, sparteine (18, 19) seems to have taken its place, both as a heart stimulant and a diuretic. Strychnine still holds its place as a circulatory stimulant. The ingestion of distilled water is indicated also for the diuretic effect—I mention distilled water as it is free from chlorides. When hiccoughing occurs, the administration of sodium bicarbonate or Hoffman's anodyne seems to be of use in allaying this grave and annoying symptom. In some instances there is a condition of apathy, a hazy mental state, with slight muttering delirium; when these symptoms manifest themselves it is well to get the patient out of bed and into a wheel chair.

Gastric lavage for vomiting, or small pieces of ice allowed to dissolve on the tongue, seems to bring about relief. When drainage has been instituted, careful watching for obstruction is imperative. It sometimes becomes necessary to perform bilateral decapsulation of the kidneys in order to restore renal function.

CONCLUSIONS.

1. Prophylactic care before operation.
2. Careful clinical study corroborated by functional tests of the renal output.
3. Comparative studies of toxic retention in the blood as well as in the urine.
4. Careful selection of the anesthetic and expediency in operating.
5. Close attention to maintenance of drainage when indicated, and to the renal output, after operation.

TUBERCULOUS INFECTION AND TUBERCULOUS IMMUNITY,

By Albert C. Geyser, M. D.,
New York,
Professor of Physiological Therapeutics, Fordham University.

I quote verbatim from an article by Dr. S. Adolphus Knopf, in the *Medical Record* for January 8, 1916, and reviewed in the New York Medical Journal for January 15th:

> According to exact statistics as well as general impressions given by men of vast experience, the majority of cases of tuberculosis in the adult have their origin in an infection during infancy or childhood. . . . Nearly all authorities consulted unite in the opinion that in order to combat tuberculosis successfully in the young and the old alike, we must diminish the source of infection in childhood.

The first part of the foregoing statement we must admit to be correct. That being so, the second part deserves closer attention. The fact is that nearly every person living in a civilized community has been infected before reaching the twelfth year of life. It naturally follows that we are all more or less tuberculous. If we are, all of us, tuberculous how can we diminish "the sources of infection during childhood"?

At this present moment the war in Europe is diminishing the sources of infection, but those who are fortunate enough to live and tell the tale will continue to be sources. What do we gain by diminishing the sources of infection during childhood, when one source is sufficient for a whole community?

May I call attention to the case of Typhoid Mary, who has the unique distinction of having infected numberless persons with the typhoid bacillus, although she herself does not suffer from the disease. In tuberculosis there may be thousands of such carriers, but their identity remains unknown.

Does the doctor mean that it is better to be infected later in life? In order to find an answer we must refer to some authorities that the doctor has apparently overlooked:

"The wild tribes in various portions of the globe and on our own account the Indians remain free from tuberculosis as long as they live isolated and do not come in contact with so called civilization. But when they do become infected, their mortality from the disease is unusually high, because they have not had time to acquire immunity and the source of the disease is usually a much more rapid one than in civilized regions . . . we must strive therefore to strengthen our rising generation in physique and in general physiological make-up and thus increase the immunity acquired by a one time attack of the disease" (1).

"Those races or groups which have long lived under conditions favoring almost continual exposure to infection, have acquired a certain degree of immunity. . . . Recovery from these mild infections which are often repeated in early life, leads to the development in the individual of an effective relative immunity of the acquired type. . . . Medical care which permits the recovery of a certain proportion of infected individuals, increases the proportion of protected individuals" (2).

"It means that the adult individual must appreciate that he probably already has acquired his infection and that he must depend for his protection, not so much upon dodging the germs as in keeping himself in good physical health" (3).

"Individuals free from tuberculous infection are very susceptible to the pernicious effects of tubercle bacilli" (4).

"Too much stress has been laid upon the infection and too little attention directed toward preventing the production of a soil which would sustain the life of the bacilli after inoculation" (5).

"The future crusade against tuberculosis will probably be directed largely against the factors which reduce resistance" (6).

"The tables sustain the assumption that infection with tuberculosis occurs early in life, . . . also that an infection of this kind confers immunity to new infection later in life, or if infection occurs the course is essentially milder" (7).

"It is every day becoming more evident that by the time our children reach maturity they are all infected with tubercle bacilli, and that therefore the attempt to protect our people against tuberculosis should not so much be against preventing an infection already and inevitably acquired, as toward protecting them from the consequences of what has already occurred and can in no way be avoided. . . . In the present state of our knowledge it is useless to attempt to protect our children against this wholesale infection because we do not know when nor how nor why it is acquired" (8).

"All civilized races long removed from infection are particularly susceptible. Some of the white races have acquired a certain degree of immunity by inheritance and almost universal infection" (9).

"A cow which reacts to tuberculin in a stable with cattle known to be free from tuberculosis, often brings about an infection of the cattle, so that ultimately they all become reactors, although it cannot be proved that the cow which disseminated the bacilli had any physical signs of the disease" (10).

"Given a virgin soil and a race of bacilli already adapted to the species, an initial infection takes place with little hindrance from the nonspecific defensive powers. . . . The ultimate survival of those who acquire a relative immunity will tend to diminish the severity of the disease, but many generations will be required to accomplish this" (11)

"I have elsewhere shown that no intimate contact is necessary to transmit the disease among persons who have not met with tuberculosis before" (12).

"Evidence that a large percentage of persons acquire a limited tuberculosis infection in early life has been accumulated and the conviction has grown stronger that a certain limited immunity is conferred as a result of these early infections" (13).

"At the Nazareth Trade School in Farmingdale, L. I., we have a general average of 400 boys ranging in ages from six to sixteen years assembled under one roof. While there are a few who show what may be termed the 'pretuberculous diathesis' the percentage of those suffering from actual tuberculosis is less than one per cent., yet according to the tuberculin test ninety-five per cent. would be credited with having the disease" (14).

"Children recover apparently from their tuberculous infection as they do from measles or scarlet

fever. There is, however, this difference. In the recovery from measles or scarlet fever the germs seem to have been destroyed in toto, while in tuberculosis the bacillus is apt to remain in the host latent, much as Spirochæta pallida" (15).

These quotations certainly throw some doubt, not only upon the possibility, but upon the advisability of attempting to "diminish the sources of infection in childhood." Since every person has been infected, he may, for all we know, be a carrier of the infection. One of the first things that we must learn to appreciate more and more is the fact that "tuberculosis" is not synonymous with "phthisis." A patient may have tuberculosis, but it does not necessarily follow that he is or ever will suffer from phthisis. Phthisis pulmonalis is a symptom complex and requires at least three permanent factors, all of them to be present at one and the same time.

First, the patient must be infected with the specific cause, the bacillus tuberculosis; second, the patient either never had an immunity because never infected, or else he has lost a previously acquired immunity; third, the patient must have either a localized anemia or a general lowered body resistance.

As we have seen from the foregoing citations, the infection with Bacillus tuberculosis is practically universal and usually confers a more or less lasting immunity.

Among wild tribes there is no immunity because they have never been infected with the specific germ. When they do become infected, phthisis occurs rapidly and usually with fatal results. Tuberculous infection is a result of civilization; all civilized nations are infected. They all have as a result acquired a reasonable degree of immunity. Civilized modes of living tend to destroy this acquired immunity. When this acquired immunity is lost the patient is apt to become like his uncivilized brother, rather hypersensitive, in a condition of anaphylaxis. This condition of anaphylaxis either creates or is preceded by a localized anemia, usually in the upper or unused portion of the lungs.

Having these three conditions, a local anemia in the lungs from nonuse, a nonimmune person or a state of anaphylaxis plus an infection with the specific cause and we have phthisis pulmonalis.

The treatment is as specific as the disease. It will take some time to rid the human mind of fads and fancies. When that time comes, phthisis pulmonalis will be treated on rational lines according to well established laws in harmony with physiology.

Phthisis pulmonalis is an easily preventable disease and certainly as easily cured as any other disease to which human flesh is heir.

EARLY SYPHILIS.

Its Clinical and Microscopic Diagnosis,

By Oscar L. Levin, M. D.,
New York,

Assistant Physician, Department of Dermatology and Syphilis, Cornell Medical School; Assistant Dermatologist, Mount Sinai Hospital, O. P. D.

Experience impresses us with the unruliness, the inconsistency, and the obstinacy of syphilis. The longer we observe these cases and the greater the intimacy with the victims, the more we appreciate the fact that a long course of intensive treatment is necessary. It is generally conceded that the prognosis is best when the treatment is given in the very early stage of the disease. It is therefore of infinite importance for the physician to make a diagnosis of beginning syphilis. This sketch is written to review the clinical appearances assumed by the chancre and to emphasize the value of a microscopic examination of material from the initial lesion for the microorganism of syphilis.

The typical chancre usually appears within three weeks of inoculation, but may occur as early as ten days after exposure. The patient usually experiences a slight localized itching and notices an erythematous spot, which gradually develops into a persistent, superficial, dark red papule. After a few days the surface epithelium desquamates and a round, superficial, dark red, sharply circumscribed, glistening erosion forms, which exudes a scanty discharge. Occasionally a beginning induration may be felt on the periphery. This is the picture usually present when first observed by the physician. It is typical. No other lesion on the penis resembles it and a positive diagnosis is confirmed by finding the spirochetes. The Wassermann reaction is almost always negative at this time.

After four or five days, the erosion tends to extend peripherally and penetrate the deeper tissues, forming a sharply circumscribed, well defined ulcer, which feels hard, firm, or cartilaginous. The induration feels as if it were about and underneath the lesion and set into the skin. When not secondarily infected, it looks clean, has sloping edges, a regular, shining, dark red floor, and exudes a profuse serous discharge containing the spirochetes. The skin around the ulcer looks blue and congested and not an angry red. The lymph nodes in both inguinal regions are uniformly enlarged, painless, indurated, freely movable, do not suppurate, and the skin over them is not inflamed.

The great majority of genital chancres occur on the glans penis, the prepuce, and the skin of the penis; the others are found scattered on the scrotal skin, the meatal mucosa, and within the urethra. In the female they may be found in the vulva, the vagina, and the cervical canal. Extragenital chancres may develop on any part of the body where the continuity of the skin is broken or on a mucous membrane.

Initial lesions vary in clinical appearance. The secretion may be profuse, scanty, absent, or dried to form a crust, and the induration may be marked, slight, or absent. The lesion, although usually single, may be multiple. It may be infected by an ordinary pus organism or by the bacillus of Ducrey, the causative agent of chancroid, and become echthymatous or a mixed chancre with suppuration of the lymph nodes. A superimposed luetic infection may cause a chancroid gradually to become indurated. In the aged, and people with chronic diseases, a gangrenous ulcer may be present.

Instead of an ulcer a round, dark red, dry, smooth, or slightly scaly papule occasionally occurs. The so called silvery spot is generally situated upon the glans and looks like the small spot left after the application of a caustic stick. Later it becomes ulcerated.

The indurations assume different forms and shapes, and are classified accordingly: 1. Laminated, in which the hardening round the chancre is thin and feels as if a disk of paper was in the superficial layers of the skin. 2. Parchment induration. The lesion feels as if it was placed on a piece of parchment. 3. Nodular is the most characteristic and feels like a cartilaginous nodule. 4. The annular induration forms a dense ring around the sore.

In detecting induration a piece of rubber tissue is placed over the lesion, which is then pinched up between the thumb and index finger. The rubber tissue should be destroyed by heat and all precautions observed to avoid infection. Induration is much more marked on the glans and prepuce than anywhere else on the genitalia or the general integument of the body.

Osler and Churchman classify chancres according to the extent and form of ulceration (simple fissures, small ulcers, giant ulcers), the depth of ulceration (erosive, ulcerative, and boring ulcers), the character of the surface (papular, squamous, diphtheroid, pustular, and papillomatous chancres), and the character of the base (foliaceous, parchment, hypertrophic, elevated, and elephantine chancres).

Genital chancres may be cōnfounded with chancroid, herpes progenitalis, folliculitis, and impetigo. A chancre occurring at the meatus may resemble a gonorrheal ulceration or when within the urethra simulate a Neisserian infection. A diagnosis of balanoposthitis is often made when the sore occurs beneath the foreskin, producing a phimosis which conceals it. In the female the chancre may cause a diffuse inflammation of the vaginal canal, which may resemble an ordinary vaginitis.

Extragenital chancres are acquired innocently or as a result of perversion. The site of the lesion often misleads the physician and syphilis may not be thought of when one of these presents itself. The general characteristics resemble those of the genital chancres, but the lesions may be confounded with epithelioma when occurring on the finger, with herpes, impetigo, or a chronic fissure of the lip and epithelioma or diphtheria of the tonsil or the pharynx. Chancres of the anus resemble chronic indurated fissures or ulcers, but when situated within the anus may not be discovered until the appearance of symptoms of the secondary stage. When a chancre occurs on the general cutaneous surface, a diagnosis of echthyma or tuberculosis may be made.

A typical chancre occurring on the genitals makes the diagnosis comparatively easy, but an atypical genital or an extragenital lesion may offer great difficulty in diagnosis. A conclusion is often impossible unless Spirochæta pallida is found. The spirochæta is always present in the chancre. It remains localized for ten hours after inoculation, when it invades the lymph vessels. The vascular system is not invaded until three weeks later. If the microorganisms are revealed in this period, intensive treatment must be instituted in order to prevent the disease from becoming general.

Spirochæta pallida or Treponema pallidum is present, not only in the chancre, but in the lymph nodes during the primary stage. It is also found occasionally in the later cutaneous lesions. It is a straight or slightly curved organism with pointed extremities. It is about seven micra long and at the most one half of a micron broad. It has from five to twenty convolutions, the average being ten. These form acute angles. In fresh specimens the organism is distinctly active and moves usually by rotating about its long axis. It may also move forward and backward with a gliding motion, or by flexion and extension of its body. Sometimes a snapping whiplike action is observed.

There are several microorganisms related to Spirochæta pallida, which when found in specimens from a suspected lesion, may cause confusion. Spirochæta refringens is larger, has a coarser contour, fewer and wavy convolutions, is more refractile, and stains more easily and deeply. Spirochæta buccalis is found only in the mouth, even in health, is thicker, has irregular convolutions, and shows snakelike or flagellating movements. Spirochæta microdentium is found in tooth deposits in children, is finer, has more regular convolutions, and is less active. Spirochæta pertenuis, which causes frambœsia tropica or yaws, is longer, measuring from seven to twenty micra, has more numerous convolutions, and its extremities are more tapering. The spirillum of Vincent's angina is found, together with Bacillus fusiformis, and shows a variable number of convolutions which are less steep and more irregular than are those of Spirochæta pallida. This spirochæta and Bacillus fusiformis are probably identical.

In examining for Spirochæta pallida in a lesion there are several methods of procedure. These are by means of dark ground illumination, India ink, and various stains. The best of these is the first. This and the India ink method depend upon the fact that light colored and unstained objects are rendered more easily visible when observed against a dark background.

In the dark ground illumination the spirochete is not only rendered visible, but is illuminated and viewed in its active motile state. This is accomplished by using a special reflecting condenser, which directs the light rays coming from a radiant of great intensity to the spirochete, which is thus intensely illuminated. At the same time the rays are prevented from entering the objective. Thus a dark background is formed.

If the suspected lesion is crusted or dried it is always advisable first to apply a sterile normal saline solution to soften and remove both the crust and Spirochæta refringens, and to increase the flow of serum. When an antiseptic has already been applied, serum may be obtained and immediately examined, but it is always preferable first to use a saline dressing for twelve hours, to insure a specimen with live active spirochetes. Precautions should be taken during the manipulations to produce as little trauma as possible in order to prevent a flow of blood, the presence of which obscures the field and conceals the organisms.

A drop of sterile normal salt solution is first placed on a slide, with which a loopful of the suspected serum is then thoroughly mixed, and the whole is surmounted with a cover glass. The margins of the cover glass should be coated with petrolatum to prevent evaporation, drying, escape of the mixture, and a possible inoculation of the examiner. Scrupulous care should be taken that the apparatus is clean. New cover glasses and slides should be used for each examination. The slightest speck of dust or the smallest scratch will scatter light of diffraction and produce a general haze over the field.

The specimen is now ready for examination. A drop of immersion oil should be placed on the under side of the slide, before adjusting it upon the microscope. The condenser should be raised until it is in contact with the immersion oil. It is best to place the oil on the slide rather than on the condenser because it eliminates the danger of bubble formation which may occur when the oil is dropped on the condenser. The light is now turned on, and the lamp inclined so that its rays are directed fully upon the plane side of the mirror of the microscope. The high power ocular is brought close to the slide and focused with the fine adjuster, and the mirror is moved into that position in which it reflects the best light.

The danger of infection should always be remembered. Immediately after use the platinum loop should be sterilized in a Bunsen flame, the saline solution should be set aside and used for no purpose except similar examinations; the specimen, after being examined, should be destroyed by heat, and the cover glass and slide should not be used again. The lesion should be dressed with a mild antiseptic, and all substances which were in contact with it burned. The microscope should be cleansed with alcohol and xylol.

It will be found convenient if the lamp is placed in a fixed position on a board base and the microscope always put on the same spot. This will save time in future examinations.

Although the dark ground illumination, as already stated, is the best method at our command, it is not always the method of choice because it requires special and costly apparatus. This is not the case when the India ink is employed. The latter method depends upon the fact that foreign substances present in the thin film of ink appear as clear spaces on a dark brown background, and it is therefore important that all such extraneous matter be removed from the ink before it is used. This is accomplished by destroying all the bacteria by sterilization of the ink with heat and throwing down all other particles by centrifugation. It is then kept in a sterile test tube in the ice box and only the upper portion is used. The best ink for this purpose is the Günther-Wagner manufactured by Grübler.

The lesion is sponged with sterile saline solution, the crust, if one is present, is softened and then gently elevated with sterile forceps. A loopful of the serum is obtained and thoroughly mixed with a drop of the India ink which has previously been placed near one end of the glass slide. The mixture is spread in a thin film by drawing the edge of a second slide over the specimen slide in a manner similar to that employed in making a blood smear. The smear is allowed to dry in the air and must not be heated. It is then examined with the oil immersion lens, and if the spirochete is present it will be found as a clear spiral space against the dark brown background. It is not necessary to use a cover glass.

Beside the dark ground illumination and the India ink methods of examination for the spirochete, there are special stains such as the Giemsa, the Coldhorn, and that originally described by Schaudinn and Hoffman, but the results are not by any means so satisfactory as those obtained by the two methods described.

In conclusion, it is emphasized that a good prognosis may be offered the syphilitic if a diagnosis is made in the early stage. The diagnosis of a chancre should be made by the clinical picture and corroborated by the microscope. All lesions on or in the neighborhood of the genitalia and all suspicious extragenital lesions should be examined for Spirochæta pallida. The examination of material for the microorganism, although simple, will at first tax one's patience. The technic is readily acquired. No time should be lost in waiting for the development of a positive Wassermann complement fixation test or induration of the lesion.

SIX MONTHS' WORK IN ANESTHESIA.*

Second Surgical Division, New York Hospital, 1915, with a Report of Endotracheal Cases to Date.

By Alma Vedin, M. D.,
New York,
Anesthetist, New York Hospital; Consulting Anesthetist, New York Infirmary for Women and Children.

The cases comprise general and gynecological surgery, as well as a small percentage of tonsils and adenoids. The routine method employed has been ether by the drop method, preceded by nitrous oxide in adults and ethyl chloride for young children. In head and neck cases, endotracheal or pharyngeal insufflation has been used, and in minor cases nitrous oxide and oxygen, or ethyl chloride. The ethyl chloride has been dropped or sprayed on the gauze covered mask, and in some cases its use has been continued as long as half an hour, always with good results. The patients have had a beautiful pink color and no mucus, and the action is very rapid, as well as the awakening. Chloroform has seldom

*Read before the Women's Medical Association of New York City.

been employed on account of the danger; a few drops have been added occasionally to deepen ether anesthesia.

Our patients as a rule suffer little from the anesthetic, many having no conscious vomiting nor nausea, and very seldom excitement or cough during induction. No preliminary medication is given. They are kept in recovery rooms adjoining the operating room until conscious.

The anesthetics are administered by the official anesthetist, the junior staff doctor, substitutes, and students, under supervision. It has been our aim to induce anesthesia as pleasantly and quickly as possible, and to keep the patient as lightly under as the operative procedure will allow, thereby reducing hemorrhage and shock; for there is no doubt that there is more oozing when the patient is completely relaxed and hence more tendency to shock.

In 656 cases where careful records have been kept there was no conscious vomiting in 334 cases, or 50.91 per cent., and 210, or 32.01 per cent, had slight vomiting, whereas 112, or 17.07 per cent had considerable long continued or late vomiting. Seventy-seven suffered from headache and 269 from varying degrees of thirst. Forty-five complained of cough, but very few to the extent that treatment had to be instituted. Thirteen of these were coughing before the operation. These data have been obtained by closely questioning the patients, and they have seldom complained of the anesthetic.

It is generally thought that without a preliminary hypodermic injection of morphine and atropine, the patient will suffer much with mucus, but we have not found this to be the case. It is only in the exceptional cases that we have been troubled with excessive mucus, and these have not been among the cases that have later developed pneumonia. The pneumonias have been studied by Dr. Frederic Bancroft and described at length by him in discussing Doctor Whipple's paper on Postoperative Pneumonias.[1] His discussion is given below.

Ether seems to us the safest anesthetic, and its administration by the open drop method the safest and most practical method for the general hospital clinic. If attention is paid to keeping an unobstructed airway, there is no respiratory strain nor asphyxia, and the patient awakens promptly, in good condition.

Postoperative pneumonias. During the year 1915 there have been fifteen cases of pneumonia in 1,413 operations, or 1.06 per cent. Of these fifteen cases seven ended fatally; a mortality from pneumonia of 46.6 per cent., or a total mortality of 0.5 per cent. In order to study and analyze these cases, a brief résumé of the history and operations performed is given. First, the fatal cases will be considered.

Case I (appendicitis with general peritonitis). A child of fourteen years had been sick three days before operation; appendicectomy and drainage under gas and ether anesthesia; time, forty minutes. Death on third day. A right lower lobar pneumonia. In this case the pneumonia was probably a manifestation of a general septicemia with the anesthesia as the exciting agent.

Case II (acute appendicitis with general peritonitis). A child eight years old, onset six days before admission. At operation the abdomen was full of pus and the child was critically ill. She continued draining very slowly until the fifteenth day, when she had sudden pains in the right chest, with bloody expectoration, all the clinical and physical signs of a pulmonary embolus. Following this, she developed signs of a lobar pneumonia and died on the twenty-fourth day.

Case III (typhoid appendicitis). Child eight years old, onset two weeks before admission; malaise, fever, acute right sided abdominal pain twenty-four hours before admission. Had vomited once. Lungs negative. Few marks suspicious of rose spots. Spleen palpable. Mass in right lower quadrant; extreme tenderness; moderate rigidity. White cells, 7,000. Polymorphonuclear eighty per cent., mononuclear twenty per cent. At operation a small gangrenous area over an ulcer in the jejunum. Cecum and appendix markedly indurated (evidently the mass felt upon palpation). Appendix removed, reenforcing suture over ulcer. Ethyl chloride and ether anesthesia. Time, thirty-five minutes. Pathological report showed typhoid appendicitis. Lobar pneumonia fourth day. Died eighth day.

Case IV. Man, thirty-five years old. Exploratory laparotomy for ruptured gastric ulcer with general peritonitis. Duration twenty-four hours before admission. Abdomen found full of fluid. No ulcer found on anterior surface of stomach. Case too ill to proceed further. Drainage. Anesthesia, novocaine one per cent., and gas and oxygen after opening abdomen, time forty minutes. Patient did fairly well for a time, but drained profusely, then developed a subphrenic abscess. This was drained by the transpleural route, after having waited for thirty-six hours for adhesions of the pleura to form. He developed a suppurative pleurisy and later a pneumonia. Death was due to edema of lungs.

Case V. Woman, aged thirty-eight years. Oophorectomy for ovarian cyst. Double salpingectomy for pyosalpinx. Gas and ether, duration forty-five minutes. Left table in good condition. Died second day with signs of lobar pneumonia. Urine negative.

Case VI (acute cholecystitis). Woman, aged thirty-eight years. Enormously fat. Cholecystostomy. Anesthesia, gas and ether changed to chloroform. Patient choked and coughed a good deal and was never thoroughly relaxed. First day signs of dullness and bronchial breathing right lower base. Died on second day.

Case VII (strangulated inguinal hernia). Man, fifty-six years old. Irreducible hernia, twenty-nine hours' obstruction, vomiting, etc. Few coarse, moist rales at both bases posteriorly. Herniotomy. Gas and ether, duration thirty-five minutes. Contracted lobar pneumonia first day, died the third.

A summary of these seven cases shows three deaths following general peritonitis. Of these three cases, one was fatal at the end of the third day, one on the twenty-fourth day, of pneumonia, secondary to pulmonary embolus, and the other died of a pneumonia secondary to a suppurative pleurisy, due to a subphrenic abscess.

The other four cases, those of typhoid appendicitis, strangulated inguinal hernia, pelvic inflammatory disease, and cholecystitis, should have been avoided.

The diagnosis of the eight cases that ended in recovery were: Chronic appendicitis, 3 cases; ventral hernia, 1 case; gastrostomy for carcinoma of esophagus, 1 case; inguinal hernia and hypertrophied tonsils, 1 case; inguinal hernia, 1 case; cholelithiasis, 1 case.

Two were lobar pneumonia and six bronchial pneumonia. Onset: First day, three cases, and one each on the second, third, fourth, fifth, and eighth days. All persisted four to eight days and subsided by lysis. X ray taken in two cases showed signs like tuberculosis.

The entire series of fifteen cases classified according to pathological lesions is as follows: Appendicitis, 5 cases; typhoid appendicitis, 1 case; inguinal hernia, 2 cases; strangulated inguinal hernia,

[1] Read before the Surgical Section, Academy of Medicine, April 12, 1916.

1 case; ventral hernia, 1 case; carcinoma of esophagus, 1 case; pelvic inflammatory disease, 1 case; peritonitis with ruptured gastric ulcer, 1 case; cholecystitis, 2 cases.

It will be noticed that every case was a laparotomy. Age: Youngest, four, eldest sixty-two years. Six varied between thirty-four and thirty-eight years. Time of operation: Shortest, fifteen minutes; longest, one hour. Average, thirty-six minutes.

Onset: Earliest, first day; latest, fifteenth day. Season of year: three occurred in March, three in August, one each in the other months, therefore the time of year did not seem to be a factor. Ten occurred in the cold months and five in summer.

Conclusion: 46.6 per cent. of our pneumonia cases were fatal. Three of these cases were in sesevere peritonitis and the pneumonias may have been of the terminal type.

The anesthesia in eleven cases was gas and ether, Bennett inhaler, followed by the drop method. Ethyl chloride and ether, 2 cases; gas and ether followed by chloroform, 1 case; local, novocaine, followed by gas and oxygen, 1 case.

The bacteriology of this series has not been studied.

The study of the bacteriology in Doctor Whipple's paper has been most instructive, and will tend to clear up the disputed question of whether the postanesthetic bronchopneumonias are true bronchopneumonias or multiple infarcts. In our series we had two cases where the x ray report was returned "suspicious of tuberculosis." Both cases later cleared up. It seemed probable that the shadows seen were multiple infarcts, rather than bronchopneumonia. If the same organism found in the mouth is later identified as the cause of the pulmonary infection, it will suggest that the lesion is a bronchopneumonia. We have x rayed our cases that had unexplained high temperatures, provided that they were in condition to move, but have not considered it advisable to x ray cases with positive physical signs.

IMPROPER CLOTHING DURING ANESTHESIA.

One of the greatest factors in the etiology of postoperative pneumonias is the operative night gown. Many of the patients entering a hospital are accustomed to sleep in heavy woolen or flannel underwear. After entering the hospital they are forced to wear these light muslin gowns split open in the back. When they are on the operating table. there is often only a couple of layers of cotton between the metal operating table and their unprotected backs. During the recovery from the anesthetic, although wrapped in blankets, they may thresh around enough again to expose their backs. There should be undershirts of different weights provided by the hospital, so that the body heat of a patient may be protected until he is well out of the influence of the anesthetic.

ENDOTRACHEAL CASES 115.

As this is a comparatively modern method of anesthesia, being first used on the human being by Elsberg, in 1910, it seems important that all cases should be recorded in order that a correct estimate may be formed of the safety of the method as well as its special indications.

The apparatus used in the New York Hospital is the Janeway, which is kept on a table specially made for it, with a closed compartment below, containing all the necessary appliances. In this way the whole apparatus can be wheeled from room to room. It has the advantage over some similar machines, that it runs without noise and so does not disturb the operator.

The Jackson direct laryngoscope and silk woven catheters are used. The patient is placed in position for operation and a small sandbag is placed under the shoulders fully to extend the head, allowing the catheter to be placed while the patient is being painted and draped; thereby time is saved. A little more time is required than with the inhalation method, however, as the patient has to be deeply anesthetized in order to insure success in intubation, and this is one reason why we have not used the method more frequently. In the beginning we used it in all kinds of cases to try out the apparatus and gain skill in intubation.

This series of 115 cases, therefore, represents a great variety of general surgical operations: For repair of hernia, 22; 11 for cervical adenitis, 12 for appendicitis, 4 for gallstones, 15 other laparotomies, 14 thyroidectomies, 2 brain cases, 2 laryngectomies, 3 resections of jaw, 4 thoracotomies, 1 resection of cervical rib, 1 resection of portion of sternum, 4 fracture cases, 1 prostatectomy, etc. They were most of them fairly long operations, 87 lasting half an hour or more. Of these, 46 lasted one hour or more, 4 being two and one half hours and over. The longest operations for an old fracture of both bones of forearm near the elbow—lasted two hours and fifty-five minutes, with the patient in good condition at the end. Only three cases lasted ten minutes or less.

Preliminary medication was given in only seven cases. Relaxation was with one or two exceptions perfect, with a lighter degree of anesthesia than with inhalation. There was very little vomiting and no throat irritation.

In a few cases, notably some goitre cases, there was a good deal of mucous secretion during anesthesia, but no aftereffects were noted as a result. One patient undergoing amputation of the tongue acquired pneumonia and died on the third day; and one patient with much hemorrhage, undergoing a tedious resection of the superior maxilla for carcinoma, died from shock within a few hours of the operation.

We consider the method especially indicated for intrathoracic work and operations upon the head and neck, where it is inconvenient for the surgeon and anesthetist to occupy the same field. In thyroidectomies it is particularly useful, because respiration is not interfered with when the trachea is pulled upon, nor can the trachea be compressed while the catheter is *in situ;* also for cases of extensive cervical adenitis where there is apt to be more or less disturbance with breathing.

It has been stated that pharyngeal insufflation is just as good and much easier of accomplishment, but, while it may be satisfactory in the majority of cases, it is not always absolutely smooth, as the catheters may become clogged with mucus and blood, if the operation is in the mouth, and the air

way may not be entirely free; whereas in the endotracheal method we know where the ether vapor is going all the time; and the method certainly has a place in thoracic surgery, brain surgery, and for lengthy operations about the head and neck.

BURSITIS SUBACROMIALIS.

Treatment of the Acute Form,

By Heinrich F. Wolf, M. D.,
New York,
Chief, Department of Physical Therapy, Mount Sinai Hospital and Dispensary.

Bursitis subacromialis has been studied by a great number of American physicians, among whom I have only to mention Codman and Brickner. They approached the subject from the standpoint of the surgeon, and among the various forms which Brickner mentions in his exhaustive paper there is nothing said of the acute form of this disease. I realize that on account of this fact many may doubt the existence of this disease and I feel obliged to prove that my statement is correct.

If we take the history of the cases of bursitis subacromialis, we find that in some of them the disease started suddenly without known cause, and was accompanied by a considerable amount of pain. After longer or shorter periods of intense suffering the acute stage passes and the patient is left with a stiff and painful shoulder.

I do not intend to go into the description or treatment of the chronic form, which has already been sufficiently discussed by various writers, but I should like to show that the initial stage of these conditions closely resembles that of a great number of cases which I have observed in my private practice and as chief of my department of physical therapy at Mount Sinai Hospital and Dispensary. Among the five or six hundred cases of shoulder disability which I have observed during the last six years, there were about forty where the history read as follows:

During or shortly after an attack of grippe or sore throat, and often without previous infection, sometimes after injury, violent pain with total disability of the shoulder developed. There is often a distinct swelling around the entire shoulder, and a very marked tenderness in the region of the bursa, which in some cases was distinctly fluctuating and yielded a serous fluid. Fever is absent in most cases, in fact, I observed it only twice and then the temperature did not reach 101° F.

Once a patient was recommended to me for treatment who suffered considerable pain in his right shoulder. The part was swollen and the bursa fluctuating. The patient appeared to be very sick; his temperature was 102° F. I came to the conclusion that the bursa contained pus and sent the patient to the hospital. After long observation and various treatments that were not successful, a puncture of the bursa was made, and pus found. At a subsequent operation it appeared that the patient was suffering from superficial osteomyelitis underneath the bursa. The patient was cured by adequate treatment. In some cases other joints were slightly involved, but the principal complaint pointed to the local condition.

DIAGNOSIS.

This affection has frequently been diagnosed as brachial neuritis. In this, however, if not complicated with other affections, the motion of the arm is entirely free; the nerve roots along the spine and the plexus brachialis are sensitive to pressure.

Hyperesthesia of the skin is absent in bursitis subacromialis acuta. In tenosynovitis the pain is restricted to movements where the diseased tendons are involved, and the tenderness is to be found only in that particular spot.

Tears of the tendon of the supraspinatus can be distinguished through the etiology, and by tenderness at the insertion of the muscle.

Gonorrheal infections can be recognized to some extent by the periarticular swelling, but the proper diagnosis can only be made by tracing the original infection. The other forms of stiff and painful shoulder differ from bursitis subacromialis acuta by its earliest symptoms.

My reasons for bringing this affection before the medical profession, are not only because it appears to be a clinical entity, similar to acute articular rheumatism, but because I have been able to find a form of treatment which has not failed me in any case. It consists of wet dressings kept on day and night, changed every twelve hours, high doses of aspirin, fifty to sixty grains daily, and very gentle massage. The latter must be done with the palm of the hand after sprinkling a good supply of talcum powder on the parts to be treated. Relief of the pain should be immediate. If this is not the case, the treatment was too severe or the diagnosis incorrect.

It has been my experience that only a combination of these remedies will give the desired result. The patients recover with very few exceptions (Case VII), within a week, when treated not later than three or four days after the onset; the improvement beginning from the first treatment. Strictly contraindicated are hot applications of any description.

Case I. Mrs. R., recommended by Doctor Reinthaler, had pain which had lasted for twenty-four hours; usual symptoms. Baking was given twice and pain increased, then the usual treatment was begun, massage twice daily; improvement showed at once and patient was well at the end of a week.

Case II. Mr. A. B., recommended by Doctor Junger, pain began about a week before, usual symptoms, patient took a few bakings, which after a slight initial improvement, increased the pain. He came to me about a week after the onset and recovered after a typical treatment of ten days.

Case III. Mr. M., recommended by Doctor Rubin, had been sick five days; severe pain in the shoulder; was treated with baking and heavy massage, which irritated the condition. Under the usual treatment the patient recovered in six days.

Case IV. Mr. R., recommended by Doctor Herman Lorber, fell sick the day before I saw him; very severe pain, inability as to motion, slight swelling. Was perfectly well after three days. Treatment was given every twelve hours. This patient had just recovered from an attack of grippe.

Case V. H. G., twenty-six years old, had tonsillitis eight days before. Two days later, severe pain in the shoulder. Active motion impossible. Region of the bursa very tender; distinct fluctuation. Ten days later, pain dis-

appeared under typical treatment and the patient returned to work.

Case VI. G. G., aged twenty-three years, jumped from a wagon five days before and struck his shoulder; swelling, restricted motion, fluctuation. On aspiration three c. c. of clear fluid was obtained. Cured in three weeks.

Case VII. S. M., forty-six years old, fell on his shoulder. Came to me, fourteen days later, for treatment; restriction of motion, tenderness of the bursa, fluctuation. Cured after seven days. Returned, three months later, with general rheumatic symptoms.

Case VIII. Mrs. K., presented before the German Medical Society, January 3, 1916, had an attack of pain in her right shoulder some years before, which left her with restricted motion of that arm. Renewed attack about a week before. X ray picture showed a calcareous deposit in the region of the bursa. After a week's treatment, pain disappeared completely, and motion returned to the same extent as before the second attack. It was evident that the calcareous deposit was the result of the first attack, owing to lack of proper treatment, and it was too deeply seated at the time of the second attack for treatment to cure.

I could cite a great number of cases from my records, but I abstain from doing so as they are practically repetitions of those already described. I wish once again to point out that I consider bursitis subacromialis acuta only a clinical entity, that I am fully aware of the fact that the same restrictions that we have to make in regard to acute articular rheumatism, hold true for these cases.

I am not in a position to say what connection the injury which I have mentioned in Cases VII and VIII, had with the development of an acute bursitis subacromialis and why aspirin had any effect, but I have noticed similar beneficial action in other traumatic cases of synovitis.

CONCLUSIONS.

1. There exists an acute form of bursitis subacromialis.

2. There are various etiological factors analogous to those of acute articular rheumatism.

3. Treatment, which hardly ever fails, consists in a combination of wet dressings, acetyl-salicylic acid, and very gentle massage.

UNILOCULAR CYST OF THE KIDNEY.

By Maximilian Schulman, M. D.,
New York.

This disease is sufficiently uncommon to make it desirable that a proved example of it be recorded. The case reported below, perhaps, has distinctive features of interest.

Case. Harry J. F., aged thirty-five years, white, native of United States, publisher, in May, 1914, applied for life insurance and was rejected because of the presence of albumin in his urine. He then came to me to be examined and advised. He felt perfectly well, except for being nervous and sleeping poorly and being habitually constipated. Had a good appetite and was of usual weight.

Family history: Mother had chronic bronchitis, with winter exacerbations. Father had hypertrophied prostate, otherwise well. Several brothers and sisters living and well. Patient had three healthy children. His wife was well and had never miscarried or aborted.

Past personal history: Variola as child. Did not remember any other children's diseases. Had been in printing business twenty years, but never had any symptoms of plumbism. Had gonorrhea seventeen years ago, requiring treatment for about a year. Then had an eruption of three days' duration, said to be due to medication. There were no other symptoms suggesting syphilis. Seldom drank alcohol, and very seldom smoked.

Physical examination: Well nourished man of good color, tongue clean and moist, teeth in good condition, and gums sound. Pharynx negative; skin clear; no glandular enlargement. Eyes; considerable myopia, pupils equal, and reacted to light and accommodation. Temperature 98° F., pulse 78, full, regular. Blood pressure, 144 systolic, 110 diastolic (by auscultation). Heart; left border in midclavicular line, sounds clear and normal. No accentuations and no murmurs. Lungs normal. Abdomen normal. Liver and spleen not palpable, no masses, no tenderness, no rigidity. Extremities normal. No scars, no varicosities; and knee jerks normal.

Urine (casual specimen), specific gravity 1.030, cloudy, mucus and some shreds, acid, albumin + cloud, moderate number of finely granular casts in sediment, sugar, 0, indican no excess. A twenty-four hour specimen delivered a few days later, contained 750 c. c., and only a trace of albumin and a few granular casts.

The Wassermann reaction in blood serum was negative.

The patient was advised in matters of diet, warm bathing, and general hygiene, told not to take his condition with too much concern, and to report periodically. He appeared about three weeks later, with urine showing only a faint trace of albumin and no casts.

I saw nothing more of him until August, 1915, when he came in from the country, complaining of headache. He then had a foul breath and badly coated tongue, a temperature of 100.5° F., and what I thought was a palpable spleen. I gave him one ounce of castor oil, took blood for Widal examination, gave him instructions looking to typhoid, and told him if he was not well and rid of his headache the following day, not to come to the city, but to call a local physician.

His Widal was negative, and I subsequently learned that he was well after the castor oil had operated.

September 21, 1915, I was called to see the patient because he had a headache of two days' duration. He had been entirely well since I last saw him in August. Except for the headache and vomiting of some citrate of magnesia which he had taken, he felt nothing wrong, though he was constipated, as usual. On examination, he had a normal temperature and pulse, and everything else negative, until I reached his abdomen. I again felt a mass under the left costal border, which, at first, seemed to be the spleen. On more careful examination, I found that he had a mass the size of a grapefruit, very hard, extending clear back into the flank, and freely movable. When I turned him on the right side, the mass would fall forward, so it would recede from the flank, extend to the right to the midline of the abdomen and down as far as the umbilicus. I could put my hand over it and under the costal arch, so ruling out the spleen. It seemed to be connected with either the left kidney or splenic flexure of the colon. In view of the great mobility and the chronic constipation, it seemed to me that the colon was the more likely site. The mass was smooth, not tender, and no friction rubs were either palpable or audible over it. Rectal examination was negative.

The urine now, was specific gravity 1.016, clear, amber, acid, faint trace of albumin, no casts, no sugar, no blood, a few leucocytes (recent attack of anteroposterior urethritis with epididymitis).

Blood, hemoglobin seventy per cent., leucocytes 13,000, and the differential count in 300 cells was, polynuclear, sixty per cent.; lymphocytes, thirty-six per cent.; eosinophiles, four per cent.; myelocytes, 0. There were no malarial organisms, and morphology of red cells was normal. Gastric analysis showed nothing abnormal in the motility, nor in the chemistry of the gastric juice, and no pyloric obstruction.

Stool was normal, and on two examinations failed to show occult blood. It was still impossible to be certain with what organ the mass was connected.

The x ray findings seemed clearly to indicate that the mass was not connected with either spleen or gastroenteric tract. It was therefore most likely that it was connected with the left kidney. An x ray plate of the lumbar region showed nothing abnormal in kidney areas.

In view of the foregoing and a urine containing

very little that was pathological, the diagnosis seemed to be brought down to hypernephroma or obstructed hydronephrosis. It was now in order to cystoscope the patient and catheterize the ureters. This was done after indigocarmin had been injected intramuscularly, with the result that a good urinary flow was observed to come from *both* kidneys, and the indigocarmin also was excreted promptly and equally from both sides. An examination of the separated urine showed on left, suspected side no blood, but an occasional leucocyte, on right, healthy side, a few fresh red cells and one clump of epithelial cells. The left ureter was injected with argyrol and an x ray picture taken. A final preoperative diagnosis of hypernephroma was therefore made and prompt operation advised.

The patient was operated on under gas and ether anesthesia. A large cyst presented which could not be delivered through the wound, and which was therefore emptied by aspiration. It was then possible to note that the cyst sprang from the lower pole of the left kidney, and that the kidney and ureter were entirely normal. A few cm. of the kidney tissue were resected with the cyst, the kidney was sutured, and the wound closed. The pathologist's report follows:

Gross specimen: Specimen consists of a portion of one kidney measuring 4 cm. by 3½ cm. by 2 cm., attached to which there is a cyst measuring 7½ cm. by 3 cm. by 3½ cm. Cyst is made up of what looks like a thin, connective tissue wall, the lining of which is arranged in elevated ridges projecting consecutively.

Microscopic examination: Cyst of kidney shows that the wall of the cyst is made up of very dense connective tissue and what is apparently smooth muscle. Cyst wall is suggestively thick. It has compressed the kidney tissue and at points the tubules make very small islands scattered throughout the tissue.

The kidney proper shows that the glomeruli are undergoing degeneration and are replaced at many points by connective tissue scattered throughout the compressed kidney. The lining of this cyst is a small, low epithelium, apparently that of the ureter. It suggests that the cyst is formed from the dilated pelvis of the ureter and is not a true cyst of the kidney.

It must be added to the pathologist's report that the cyst *was not* "formed from the dilated pelvis of the ureter," for the ureter was entirely normal.

The fluid contained in the cyst was cloudy, light, and amber colored, was sterile, and contained no urea.

The patient made a smooth recovery.

The urine (patient on full diet), examined about three months after the operation, was of specific gravity 1.026, and contained a trace of albumin and a few hyaline casts, this being about the same as prior to the operation.

The constipation is considerably reduced, though the patient still requires a small dose of some laxative every second day. The general condition is excellent.

1845 Seventh Avenue.

A Case of Palpebral Chancre.—Donald M. Livingstone in the *Lancet* for May 20, 1916, remarks that this condition is rare and the diagnosis is difficult for some weeks unless spirochetes are found in scrapings or the Wassermann is positive. Rapid healing under salvarsan is proof of its luetic nature.

LABORATORY FACTS IN POLIOMYELITIS.

Observed in the Willard Parker Hospital.

By S. R. Klein, M. D., Ph. D.,
New York,
Director, Norwich Pathological and Bacteriological Laboratory.

While doing laboratory research work in the Willard Parker Hospital on infantile paralysis cases, I have had an excellent opportunity to observe some remarkable facts, mostly based on laboratory diagnosis. During my stay there, nearly 400 children were brought in, fifty per cent. of them having been diagnosed as doubtful cases. The death rate was very low, thanks to the exact, thorough, excellent management and clinical treatment extended to the unfortunate little creatures by physicians and nurses. I can really say that the city of New York should be congratulated on having such an institution as the Willard Parker. In nearly every case was a urine and blood examination performed, but, of course, no special findings could have been recorded, except that every urine contained albumin, more or less, with sugar regularly absent. Urea, as usual under inflammatory conditions, was higher—about three to 3.5 per cent. Anuria was almost absent, except in most of the fatal cases. Differential blood count showed mostly from eighty to eighty-five per cent. polymorphonuclear cells, the rest of them small and large lymphocytes. No bacteria, of any kind, were found. I have tried to find the Ehrlich granulations, but failed to do so. The Schick test was made in many cases suspected of having remains of diphtheritic microorganisms, and reported as negative.

In regard to lumbar puncture I would like to say that, according to Peyton-Rous, the average protein content is 0.3 grain to the litre, but in these cases it varied from one sixth to three eighths of a grain. The normal pressure in the subarachnoid space is estimated at thirty to fifty mm. of water, but in the fatal cases it varies from 120 to 180 mm. In a very few cases it went as high as 300. At the height of the disease the fluid is grayish yellow, and turbid. On standing, in the case of a purulent fluid, a yellowish, homogeneous, and viscid deposit collects at the bottom of the tube, while the supernatant fluid becomes somewhat clarified. A fibrin reticulum is occasionally seen floating in the fluid or adherent to the tube. Along the sides of the tube a deposit of fine yellow flakes resembling sulphur particles may form.

Microscopically, the protoplasm looks homogeneous, nongranular, and vacuolated. The chromatin network of the nucleus is not sharply stained. At times the nucleus disappears. Some of the cells are so markedly degenerated that only a cellular débris remains. The lymphocytes are usually present in the proportion of ten to fifteen per cent. As a rule, they show less degeneration than the polymorphonuclears.

Frequently there are vacuoles which contain one or more ingested cells. These large cells are derived from the connective tissue and adventitia of the bloodvessels of the meninges. Concerning micrococci, I found these microorganisms in considerable abundance. We should accept definitively the Weichsel-

baum micrococcus as the only microorganism found in the spinal fluid, producing inflammatory processes in the cerebrum, cerebellum, and cord. No other microorganism has ever been found in the fluid since Quincke made the discovery. This is a fact and we should accept it as the only important achievement of that kind of research work.

During my stay in the hospital one of our interns found a dead cat in the same room where he took a child affected with infantile paralysis. Remarkable in the case is that the child recovered after a while. The autopsy performed on the cat showed the spinal cord very soft, also two ventricles of the cerebrum. The lungs showed bronchopneumonia. We stained the cord and cerebellum by the Giemsa method and alcoholic solution of fuchsin and methylene blue. A tremendous number of lymphocytes were found and micrococci which exactly corresponded with those of Weichselbaum.

In regard to bacteriolysins, bacteriotropins, and antiendotoxins, I would say that the first ones mentioned exactly inhibit the growth of the micrococcus—that the bacteriotropins markedly stimulated phagocytosis. Antiendotoxins gave very little encouragement in regard to the usefulness of serum. If I mention that one monkey was treated with spinal fluid, but unsuccessfully, I think I have mentioned all the facts we found in infantile paralysis cases. All other research work proved to be negative in result.

Foot of East Sixteenth Street.

Contemporary Comment

California Mineral Springs.—The cry of "see America first" has been heard throughout the land, remarks the *California State Journal of Medicine* for June. But the European war and the fear of submarines did more than any amount of advertising to convince the traveling public of the wisdom of heeding the cry. So, too, with our mineral springs, with which this country, like Europe, is richly endowed. The waters of the European spas can all be duplicated in the United States. Some of them are possibly superior to those of Europe. The great trouble with the springs in this country is that no real effort has been made to induce people to go to them. In this State we have no place that really meets the requirements of a first class resort. First class hotels, attractive grounds with an abundance of carefully laid out walks, convenient drinking places, proper bathing facilities, carefully planned institutions for hydrotherapy and mechanotherapy—all these are needed if a resort is to attract people, or if it expects the support of the medical profession.

It is possible that the profession does not thoroughly appreciate the value of our mineral springs. Too often are we apt to attribute the benefit derived by patients at distant resorts to the change of climate, the interesting trip, the freedom from household or business worries or duties, discounting the effect of the waters, often because the drinking of the same waters after they have been bottled is devoid of results. Recent observations would seem to lend truth to the belief that waters drunk or bathed in, at their source, are better by far than the bottled product. The discovery of radium in many of the waters in the United States as well as in Europe explains why this may be true.

In Europe, the various municipal and state governments have done much to develop their resorts, not only because of the desire to lessen the suffering of humanity, but because of the revenue ultimately derived therefrom. A few years ago, the State of New York purchased Saratoga Springs. It obtained the services of experts to aid in the restoration of the springs, which had suffered at the hands of shortsighted commercial interests. It has spent considerable money; it is today beginning to reap its reward; physicians are studying its waters; they expect to find that they are as efficacious as those of Nauheim, Vichy, Kissingen, etc. It will not be long before the cardiac, the nephritic, the gouty, the rheumatic, will be taught to "drink and bathe in America first."

In California we have numerous springs. None of them may be said to be properly managed. They not only lack many of the essentials necessary for successful handling of patients, but no attempt is made to run them on a scientific basis. By their extravagant claims and literature, they create distrust rather than confidence in the minds of the profession.

Might it not be well if our most active and very efficient State Board of Health, among its many other duties, took it upon itself to investigate our California springs, and make recommendations so as to induce private interests, or failing in this, perhaps the legislature, to improve our resorts and place them on a proper basis?

Old Time Courtesy.—History records that in the good old days, a doctor, in the employ of an insurance corporation, desiring to visit the patient of another physician would seek the permission of the latter, and that this privilege was, in most instances, most graciously accorded him. It is a noticeable fact, however, in these days, that such courtesy is often entirely lacking, especially in the newly hatched doctor who has only just begun to grow his pin feathers.

It is no uncommon thing, remarks the *Medical Adviser* for June, 1916, for us to learn that between calls one of these phenomena has blundered in upon our patient with an authoritative air which would do justice to the president of the company, and proceeded to inform him that he was there for the purpose of ascertaining the extent of his injuries, general condition, etc. He insolently inquires into the treatment, comments upon it at will, disturbs or removes bandages, and frequently leaves the unfortunate person in doubt as to the efficiency of the attending physician.

As matters in this regard seem to become worse as time goes on, we suggest that it might be well for our medical colleges to add another department to their curricula whereby a couple of hours a week during the senior year could be devoted to instruction in professional deportment for the benefit of those who are naturally lacking in that qualification.

NEW YORK, SATURDAY, JULY 29, 1916.

THE TREATMENT OF INFANTILE PARALYSIS.

The reported successful use of adrenaline in the treatment of acute poliomyelitis will meet an urgent need if a number of recoveries sufficient to afford a fair test can be recorded. Indeed, in a recent editorial article (NEW YORK MEDICAL JOURNAL, July 8, 1916) we referred to the unfortunate paucity of curative measures at our disposal. In the recently published edition of Osler and McCrea's *Modern Medicine*, Farquhar Buzzard speaks in the same vein when he states: "We are unacquainted with any method of combating the acute attack and must be content to treat the initial stage similarly to that of any acute infective disease. When the disease is epidemic," continues this distinguished neurologist, "and constitutional disturbances suggest the possibility of an attack, the administration of hexamethylenamine is worth a trial." The same reserve was fittingly observed by Simon Flexner in his recent public address, when speaking of the shortcomings of hexamethylenamine, and of his own serum, he said: "The experiments have not yet reached the point where the new drugs are applicable to the treatment of human cases of infantile paralysis."

We urge that a fair and impartial trial be given to adrenaline, not only because its use was suggested by so competent an authority as Meltzer, and because of the favorable results obtained in forty-one cases by Doctor Bermingham at the New York Throat, Nose, and Lung Hospital, but on account of its intrinsic merits as a pharmacological entity. To realize its possible worth, however, its users must place the problem on a higher scientific plane than the reported statement that the direct injection of adrenaline into the spinal canal acts "as a wonderful tonic" when "reaching the nervous tissues" and "removes pressure from them," and thus "places nature in a position to do the rest." Much evidence is available to show that we have, in all probability, in adrenaline, thus used, *a direct activator of the antitoxic function of the blood* in the central nervous system, the main seat of morbid activity of the veins.

Brown-Séquard, Abelous, Langlois, Albanese, Zucco, Charrin, and others have long emphasized the importance of the ductless glands as factors in the active protection of the body against disease. While Charrin, nearly twenty years ago, wrote, "As to antitoxic functions, one may depend upon a series of viscera, first of all the liver, the pituitary, the adrenals, the pancreas, the kidneys, the spleen, etc.," Albahary, as recently as 1913, in a paper read before the Paris Biological Society, stated that "as regards the neutralizing secretions that the organism can oppose to the action of a toxin in general, we know today that this role belongs mainly to the ductless glands." Sajous, however, identified the role of the adrenal secretion in the process as that of a catalyzer, the purpose of which is to activate oxidation and thus enhance the antitoxic power of the digestive ferment which, both in phagocytes and the plasma, endows the blood with defensive properties. The influence of the adrenal principle on oxidation was confirmed, in 1912, by Bernstein and Falta; while the labors of Abderhalden have confirmed the view that a digestive ferment is the active protective agent in our defensive functions. Briefly, the evidence goes to show that adrenaline should not be looked upon as an antibody, but as an activator of antibodies.

How does the adrenaline penetrate the central nervous system to enhance the antitoxic power of the blood therein? On the basis of Ehrlich's methylene blue injections, Sajous, in 1903 and 1907, pointed out that bloodplasma laden with the adrenal principle circulated in the nervous elements, traveling upward as does tetanotoxin. Lichwitz, in 1908, confirmed this view, having also observed that "adrenaline traveled from the lower extremities to the

upper when these were only connected by nerves." Recently the presence of adrenaline in nerves was likewise discerned by Macallum, of Toronto, with the aid of silver nitrate solution injections.

This evidence, to which much could be added, will suffice to indicate that we may have in adrenaline the keynote for a successful treatment of acute poliomyelitis. It will undoubtedly increase the defensive reactions of what active antibodies are formed. This suggests that *it might sufficiently increase the activity of Flexner's serum to give it the potency it needs* to render it effective, not only very soon after infection, but as long as the latter is active. That the hexamethylenamine wisely given simultaneously by Doctor Bermingham is aided indirectly by the adrenaline, is also probable.

SUMMER CAMP SANITATION.

Whether the summer camp idea for city people is ultimately to turn out to be a good one for the health and well being of those in need of them, and serve as the best means of recuperating after the usual high pressure of urban life, depends entirely upon its proper development along the lines of sanitation. In the abstract, the camp idea is most excellent. It is an advance upon the stereotyped summer hotels with their conventional and tiresome social life, monotonous and unwholesome menus, crowded accommodations, and burdensome personal display. Besides, even in the best resorts the sanitary conditions are far from ideal. Health authorities have continually to enforce the simplest sanitary measures. The usual autumnal increase of typhoid in large cities, where the water and food supplies are tolerably free from possible sources of infection, is summer resort exportation. The problem is still so little under control that health authorities advise antityphoid vaccination as the only measure of safety.

Moreover, it is a fallacy not yet outgrown that country life is more healthful than city life—regardless of the improvement in sanitation of urban communities. Often the strenuous social life of summer resorts allows less time in the open air than is really needed, and is without the advantages of personal comfort offered in the city. Large cities like New York are rapidly assuming the roles of first class summer resorts, with a maximum of diversion, relaxation, and safety. The health of large cities is better than of smaller ones; of small cities better than towns; of towns better than of rural communities. Health authorities in large communities are well organized and well financed and efficiently handle the sanitary problems. There is less opportunity for specific infections. For the same reason the morbidity and the mortality from nearly every disease is less in the city than in the country. On the other hand, country life may be of great benefit because of the change and relaxation offered. Change is a great rejuvenator. Open air is perhaps the best stimulant. The isolated camp offers advantages in the way of rest and repair for the overspeeded faculties. The sanitary problems in the isolated camp are intrinsic, and comparatively insignificant; but the crowded camp sites, situated not very distant from large communities, present a much larger sanitary problem than is usually realized. The opportunities for infection are numerous. Here, if anywhere, antityphoid vaccination for prospective campers should be especially urged.

The camp problem is perhaps the largest problem of army mobilization. Its poor development in the Spanish-American War was the cause of very high typhoid mortality. The success of army mobilization depends largely upon its sanitary organization. It is a medical engineering problem on a large scale. Likewise, large civilian camp sites should be laid out primarily from the sanitary standpoint. In poorly controlled camp sites the sewage disposal is the crudest, food preparation of the poorest, and necessary comforts are absent. Camp sites that give the impression of being unclean should be avoided. The gain from living out of doors, with plenty of exercise is not sufficient to overcome the loss entailed by general unsanitary conditions, poor food, lack of comfort, and small protection against cold and rain.

The camp tent is not at all ideal for sleeping purposes. The air allowed in through the partly opened tent flap, which is usually closed during inclement weather, is hardly sufficient, and not at all equal to the generous supply allowed by open windows or the artificial methods of ventilation which obtain in the city.

Then, too, every change, such as is entailed in camping, has a "negative phase," which those who need the camp life most cannot afford. Perhaps their whole vacation time does not extend much beyond this period, and they are, therefore, rather harmed than benefited. It must be remembered, especially by those who are inclined to condemn the niceties of city life, that they are evolutionary developments and not regressions. They have been large factors in increasing the span of life. While it is true that urban life has many vices, they are not to be balanced against the unsanitary conditions of primitive life which the camper is trying to mimic. The camp idea is a good one, but needs development on a large scale. Its primitiveness must be modernized, so to speak, before it can be unqualifiedly approved by the profession as a therapeutic measure.

THE PREVENTION OF AMEBIC DYSENTERY.

Amebic dysentery since the beginning of the European War has been thoroughy studied and our knowledge thereof considerably increased. While the allied troops were stationed in and about the Dardanelles, this form of dysentery was rife and a good many points respecting the treatment and prevention of the malady were unveiled, while other points concerning which knowledge was vague were illuminated. Perhaps the most important feature has been the recognition that emetine is the only drug which exerts any specific influence, and that it is of the utmost importance to give such treatment thoroughly in all cases before discharge from hospital. Efficient treatment of this character not only benefits the patients but prevents them from becoming carriers. Even when a patient has become a cyst carrier, as a rule he can be rendered noninfective by the administration of emetine combined with magnesium sulphate in doses of two drams every four hours.

It has been proved in Egypt—and this is referred to in a memorandum on the prevention of amebic dysentery published in the *British Medical Journal* for June 24, 1916, by J. Gordon Thompson and D. Thompson—that flies are capable of ingesting cysts of the pathogenic entamebas from infective material and depositing these in their feces on food. Furthermore, it has been discovered that the cysts of Entamœba histolytica will persist for a month, and much longer under conditions in which the stool is not allowed to dry too much. For instance, it has been shown that the pathogenic cysts in feces well diluted with fresh drinking water persist for weeks, and this fact has likewise been proved in the Central Laboratory in Egypt.

Consequently it is obvious that in order to prevent the spread of amebic dysentery one of the first and most essential steps to be taken is to dispose of feces in such a way that flies can have no opportunity to alight and feed on them. The authors mentioned above recommend for this purpose, in the absence of a flush water system, either flyproof latrines or metal buckets containing kerosene or some antiseptic. Kerosene wards off flies, and it is inflammable and assists in the incineration of the feces later on.

Among preventive measures which may be advocated are thorough and rapid disposal of horse dung and refuse, in order that flies may not be provided with favorable breeding grounds. Water supplies should be carefully guarded, and fly screening and destruction of flies should be carried out in the most energetic fashion. Cases of amebic dysentery should be isolated as much as possible in special wards of hospitals, and early and thorough emetine treatment should be proceeded with at once in all suspicious cases.

With respect to amebic dysentery, however, as in so many diseases, flies appear to be the chief factors in the spread. *Delenda est musca* must be the battle cry of sanitarians who are striving to wipe out, or at any rate, to curb various deadly epidemic maladies.

THE MIDWIFE.

The midwife is with us and in increasing numbers. She is not new to the old world. She existed in Egypt before the days of Moses. In the East and in Europe up to the middle of the sixteenth century all women were delivered by midwives. In the seventeenth century schools were established for their special training and in the past fifty years they have, on the continent, been under state control; in most European countries a thorough training is required, which sometimes covers a period of two years. In at least one country, Holland, midwives or a certain number of them, are taught at the expense of the state, in order that they may better serve the people of the rural regions.

Some of our own States hold examinations and have certain requirements of training, and in at least one city, New York, there is an excellent school for midwives. Since they are likely to become more and more a part of our national life, it behooves all our States to be alive to the need of seeing that the midwife in her line comes up to as high a standard of excellence as is demanded of the physician and that she has ample opportunity for the best of training.

The midwife fulfills a want among the poor, and cannot be replaced by the physician, for she is doctor and nurse combined and gives her services in both capacities at a price lower than the doctor can afford to charge.

It is not to be wondered at, therefore, that in some of our cities a fourth of the children are born into their hands. As with physicians, there are good and bad midwives, well trained and ill trained, experienced and inexperienced, yet, in comparison with the physicians, their work seems not to suffer, for statistics of one of our American cities show that of the cases of puerperal infection, about half occurred in the women delivered by physicians and half in those attended by midwives. These figures should obviously be judged in the light of the character of the clientele of the two classes of practitioners, for those assisted by the midwives are undoubtedly more immune to infection, but, nevertheless, considering the amount of her training, the

midwife stands the comparison well. Doubtless too frequent interference with the course of nature —meddlesome midwifery—on the part of the doctor has much to do with this statistical reproach.

PHYSICAL TREATMENT FOR DISABLED SOLDIERS.

Major L. Haden Guest, R. A. M. C., has sent to the *Lancet* some notes on the treatment by mechanotherapy at the Hôpital anglais in Nevers, an Anglo-French hospital established under his direction in November, 1914; they appear in the issue for July 1st. The treatment is carried out in a separate building by Dr. L. J. Phelan, an American practising in Paris as an expert in applied exercises, movements, and massage. He employs a minimum of mechanical apparatus of the Zander type and a maximum of use of elastic cord exercisers. The latter have the great merit of economy, as the cost of the apparatus for the treatment of 100 patients daily need not exceed $1,000.

The apparatus consists of a number of rubber cords and pulleys, and by adapting the position of the patient and the exerciser and by attaching the exerciser either to the hand or foot a very large variety of movements can be obtained. Special apparatus can be made for individual finger movements, flexion and extension of wrists, pronation and supination, etc. The main characteristic of these apparatus is their simplicity. Movements of the hip are obtained partly by application of the exerciser to the foot and partly by the use of an inclined plane on which the patient lies. The plane is movable on runners placed below it and the patient pushes himself up by pressure with his feet. For passive movements of the ankle and knee in cases of great stiffness a mechanical apparatus on the Zander pattern cannot be dispensed with.

Treatment is given daily, with an average duration of ten minutes, but a number of cases can be treated at the same time. The length of treatment required by individual cases varies much with the nature of the injury and the condition of the patient, but as a rough guide to the duration of treatment the following figures may be given: Injury of hand, one week; wrist, one to two weeks; elbow, one month; knee, one month; adhesions (not affecting a joint), two to three weeks. At Nevers there have been so far forty per cent. of cures, forty per cent. greatly improved, and twenty per cent. not benefited. The possibility of progress or of cure can usually be discovered in from two days' to a week's treatment. Cases for treatment should be sent as soon as possible after any open wounds have healed.

News Items

Errata.—By a regrettable oversight, two serious mistakes occurred in the original communication by Dr. M. Neustaedter on Infantile Paralysis, which appeared in our issue for July 22d. Page 146, line 7 should read 75.4 per cent. instead of 5.4 per cent.; page 146, third paragraph, line 12 should read 900 instead of ninety cells per c. mm.

New Name for the International Health Commission.—Announcement is made by the International Health Commission of the Rockefeller Foundation that its name has been changed to International Health Board of the Rockefeller Foundation.

Infantile Paralysis Clinic at Lebanon Hospital.—Dr. Charles Herrman, of 250 West Eighty-eighth Street, New York, announces that he will hold a clinic on infantile paralysis at the Lebanon Hospital, Monday afternoon, July 31st, at three o'clock. Physicians of the borough of the Bronx are cordially invited to attend.

Old Dominion Medical and Surgical Society.—At the annual meeting of this society, held at the Bay Shore Hotel, Buckroe Beach, Va., Monday and Tuesday, July 17th and 18th, the following officers were elected: Dr. J. J. France, of Portsmouth, president; Dr. J. B. Darden, of Petersburg, vice-president; Dr. R. A. Deane, of Victoria, recording secretary; Dr. J. H. Blackwell, Jr., of Richmond, corresponding secretary; and, Dr. R. E. Jones, of Richmond, treasurer. Next year's meeting will also be held in Buckroe Beach.

The Tuberculosis Movement.—Statistics compiled by the National Association for the Study and Prevention of Tuberculosis show that nearly 3,000 agencies are now listed in the fight against tuberculosis in the United States, an increase of 1,600 per cent. since 1904, when the national welfare on this disease was started. The list includes 557 sanatoriums and hospitals, 158 tuberculosis boarding houses, 90 hospitals for the insane, and 35 penal institutions making special provision for tuberculosis, 455 dispensaries, 310 open air schools, and 1,324 antituberculosis associations and committees. To these are added 158 Canadian institutions and associations, making a total of 3,087.

Sir William Ramsay Dead.—Sir William Ramsay, the discoverer of argon, neon, xenon, and krypton, gaseous elements, who occupied a commanding position in the world of chemistry, died at his home in England on July 23d, at the age of sixty-two years. He received the Nobel prize in chemistry, in 1904, had been president of the Seventh International Congress of Applied Chemistry, and of numerous scientific associations, and was a member of some fifty scientific academies and organizations in different parts of the world. He lectured at Johns Hopkins University and before the Lowell Institute some years ago. In collaboration with F. Soddey he succeeded in transforming radium into helium.

Appointments in the Medical Reserve Corps of the Navy.—At the examination recently held in various cities throughout the United States the following named medical men successfully passed the examination for appointment as assistant surgeon in the Medical Reserve Corps, with a view to subsequent examination for appointment in the Medical Corps of the Navy: James A. Halpin, M. D., Washington, D. C.; William D. Heaton, M. D., Wahoo, Neb.; Aubrey M. Larsen, M. D., Salt Lake City, Utah; Lincoln Humphreys, M. D., Argenta, Arkansas; Theo. Edward Cox, M. D., Cleveland, Ohio; Arthur W. Hoaglund, M. D., Minneapolis, Minn.; Carroll H. Francis, M. D., Camden, N. J.; Harold L. Jensen, M. D., San Francisco, Cal.

Federal Quarantine in Infantile Paralysis.—The United States Public Health Service has published a notification that no children under sixteen years of age will be permitted to leave New York city for interstate travel without both a Federal and a city department of health certificate. Before such certificates are issued children will be carefully examined by the health authorities. Numerous cities have announced the establishment of a rigid quarantine against children coming from New York city or from infected portions thereof. California has quarantined against all persons from New York who are not provided with authoritative health certificates. The railroads have advised against taking children on excursions, and railroad officials have been instructed to aid in carrying out quarantine regulations

The American Hay Fever Prevention Association met in annual session in New Orleans in June, and elected the following officers: President, Dr. William Scheppegrell; honorary vice-president, Dr. Rupert Blue, surgeon general, United States Public Health Service, Washington, D. C.; vice-president, Colonel George McC. Derby, U. S. A.; recording secretary, Joseph B. Bassich; corresponding secretary, Dr. N. F. Thiberge; treasurer, J. D. O'Keefe, vice-president, Whitney Central Bank and Trust Company.

New Head to the Union Medical College, Pekin.—Dr. Franklin C. McLean, of New York, hitherto an assistant resident physician in the hospital of the Rockefeller Institute for Medical Research, has accepted an appointment by the trustees of the Union Medical College, Pekin, China, to the professorship of internal medicine in the college. Doctor McLean will also be the head of the Union Medical College, which is one of the institutions of the China Medical Board of the Rockefeller Foundation, and he is now going to Japan, Korea, and China as a representative of the board.

Appointments to the Faculty of University and Bellevue Hospital Medical College.—The following appointments have been announced: Dr. Joseph B. Bissell, Dr. Thomas A. Smith, Dr. Walter C. Cramp, and Dr. Arthur M. Wright, clinical professors of surgery; Dr. William C. Lusk, professor of surgery; Dr. W. Howard Barber, chief of clinic, department of surgery, college dispensary, and instructor in surgery; Dr. George Francis Cahill, instructor in surgery; Dr. Theodore J. Abbott, clinical professor of medicine; Dr. Hubert V. Guile, instructor in medicine; Dr. Benjamin M. Levine, clinical professor of cancer research; Dr. Charles Krumweide, assistant professor of bacteriology and hygiene; Miss Mary Smeeton, instructor in bacteriology.

Splendid Cooperation from Private Hospitals in the Management of the Infantile Paralysis Epidemic.—The number of private hospitals in the city, cooperating with the department of health in caring for infantile paralysis has grown to 24. Of these St. Peter's in Brooklyn now has fifty patients, the New York Nose, Throat, and Lung Hospital has 38, the New York Orthopedic 33, St. Francis (in the Bronx) has 32, Mt. Sinai has 19, St. Vincent's in Manhattan has 15, and St. Vincent's in Richmond has 4. Others in the list bring the total number of patients cared for in these private hospitals (July 19th) to 245. Total cases in hospitals, 1,134; department hospitals, 765; other city hospitals, 84; private hospitals, 245; Swinburne Island, 40.

Red Cross Christmas Seals for 1916.—The printers have begun work on the Red Cross Christmas seals and will soon be turning them out at the rate of several million a day, announces the National Association for the Study and Prevention of Tuberculosis. Orders will be filled in the order of their receipt.

The 1916 seal was designed by Mr. T. M. Cleland, of New York city. It shows a Santa Claus in red on the green background of a centre panel. Santa Claus has a pack on his back bearing a red cross. The lettering A Merry Christmas and A Happy New Year is carried vertically up and down the sides of the seal. The date and the words American Red Cross, are at the bottom of the seal. The poster effect of this seal is striking and makes an unusually handsome design.

Liability of Health Departments.—The Supreme Court of Kansas has decided that a city is not liable in damages for injury resulting from the negligence or misfeasance of officers or employees of the city health department while enforcing laws or ordinances for the protection of the public health. A patient in a city isolation hospital suffered from blood poisoning as a result of getting into his foot a splinter from the floor. He alleged that the city was negligent in maintaining the floor in a defective condition, but the court said that "the duty of a municipal corporation to conserve the public health is governmental, and it is not liable for injuries inflicted while performing such duty." The opinion is published in the July 14, 1916, issue of *Public Health Reports* of the United States Public Health Service.

A Prize of 50,000 Francs for the Best Mechanical Hand Apparatus.—A generous donor who wishes to remain anonymous has offered to the Société nationale de chirurgie, a prize of 50,000 francs to be handed over to the maker of the mechanical apparatus best supplying the place of the hand. All competitors must belong to allied or neutral nations. They are to present to the society mutilated men who have been using their apparatus for at least six months. The Société de chirurgie will experiment with each apparatus on mutilated men for the length of time it thinks fit. The apparatus rewarded is to remain the property of its inventor. The competition will be closed two years after the end of the war.

MM. Faure, Kirmisson, Quenu, Rieffel, and Rochard, who make up the committee elected by the Société de chirurgie, inform the public of the condition of the competition as stated by the donor, and beg all persons wishing to compete to send their memoirs and apparatus to M. le Secrétaire Général, Société Nationale de Chirurgie, 12, rue de Seine, Paris, France.

Poisons and Habit Forming Drugs.—Martin I. Wilbert, technical assistant in the hygienic laboratory of the United States Public Health Service, has compiled a digest of the laws and regulations relating to the possession, use, sale, and manufacture of poisons and habit forming drugs, enacted during the years 1914 and 1915, and now in force in the United States. The extracts from and the references to the several statutes have been arranged under the following headings: Sale and use of poisons; sale and use of cocaine and narcotics; drugs to be announced on label; poisons in articles of commerce; occupational intoxications; methyl alcohol; sale and use of intoxicating liquors; practice of pharmacy, and standards of drugs. This arrangement has been found to serve well as a basis for the analysis of laws designed to restrict the manufacture, sale, and use of poisons and to facilitate a comparative survey of the legislation enacted during any given period of time. During the legislative year ending in 1915, some form of legislation relating to the manufacture, sale, and use of poisonous materials, was considered in the forty-nine States, territories, and possessions of the United States, and in the majority of instances the bills presented were enacted into law. This pamphlet is Reprint No. 330 from *Public Health Reports*, and was published as a supplement to *Public Health Bulletin No. 56*. Copies may be obtained from the Superintendent of Documents, Government Printing Office, Washington, D. C., at twenty cents a copy.

$100,000 to Be spent on a New York or Massachusetts Town to Control Tuberculosis.—Intense rivalry is being exhibited between towns in Massachusetts and New York in their endeavor to secure a fund of $100,000 which is to be expended during the next three years in an effort to control the spread of tuberculosis by the National Association for the Study and Prevention of Tuberculosis, as announced in a bulletin issued by that organization.

More than fifty different towns and villages, ranging in population from four to ten thousand inhabitants each, have been suggested as possible places for the experiment, and the State Charities Aid Association of New York, the Massachusetts Department of Health, and the local organizations in many of the towns are urging their claims with vigor. Among the towns which are being considered carefully are Canandaigua, Johnstown, Patchogue in New York; Framingham, Winchendon, and Norwood in Massachusetts.

The preliminary committee appointed to select the place consists of Dr. Edward R. Baldwin, of Saranac Lake, President of the National Association for the Study and Prevention of Tuberculosis, as chairman; Dr. Lee K. Frankel and Mr. Homer Folks, of New York; Dr. Arthur K. Stone, of Boston; Dr. Stephen J. Maher, of New Haven; Dr. William Charles White, of Pittsburgh, and Dr. Charles J. Hatfield, of New York, executive secretary of the National Association for the Study and Prevention of Tuberculosis, as secretary. The committee has chosen Dr. Donald B. Armstrong, of New York, as executive officer of the experiment.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Thirtieth Communication.

DRUGS AND DISEASE.

In considering the treatment of specific disease, the pharmacologist is frequently confronted with the fact that modern clinical treatment is far from being determined by laboratory findings—that when it is not frankly empirical, it is not always demonstrably rational. Some pharmacologists are inclined to rail at their clinical brethren, and denounce in no uncertain terms the apparent obtuseness of practitioners who continue to ignore the findings of the laboratory of pharmacodynamics; but it must be admitted that the conclusions from the laboratory are strictly of those conditions only which pertain to the laboratory. Conditions identical with those of the laboratory do not exist in the hospital, therefore the pharmacologist may not justly say that his drug provings on a healthy cat necessarily demonstrate a true indication for that particular drug for a sick baby; the data obtained undoubtedly strongly suggest discreet possibilities, but do not amount to a demonstration of proved efficiency in any particular disease.

Neither is the clinician justified in ascribing alterations of symptoms to a particular favorite drug unless by the careful study of many cases, in which study strict laboratory methods are used, he can legitimately prove his asserted drug action is a constant one under given conditions. Here, it must be confessed, exceedingly few such scientific observations in hospitals have been made; consequently, at present practically all statements concerning pharmacodynamics are founded upon incomplete data. The pharmacologist must needs be critical and show wherein modern treatment stands in need of further experimentation, yet he may be constructive in showing wherein possibilities exist.

TYPHOID FEVER.

Aside from the use of serum, where potent antibodies are introduced, the treatment of typhoid is symptomatic. If cardiac weakness supervenes, there are two drugs of known value which may be used, caffeine and digitalis; the caffeine may be used to correct a thin, weak heart beat, whereas digitalis is of service to restore regularity, the dose of either to be carefully regulated just to meet physiological need. Some texts as recent as last fall recommend strychnine, alcohol, and ammonia as cardiac stimulants in typhoid fever; yet, so far as we have ascertained, strychnine increases neither force nor frequency of heart action, and both alcohol and ammonia act reflexly only through irritation of the gastric mucosa, with aftereffects from alcohol that may easily prove prejudicial.

The various antipyretic drugs should be tabooed in cases like typhoid, where cardiotoxins may accumulate rapidly in the blood stream. The temperature may be best controlled by facilitating rapid radiation from the skin area by frequent spongings with cool water, the temperature of which must be adapted to the age and vitality of the patient and to the exigencies of the hour.

The use in typhoid fever of intestinal antiseptics is based more on fervent wish than on trustworthy demonstration. Are not all these antiseptics cleft in the stomach or duodenum with resulting systemic absorption of the products? Could the phenol split off from salol be germicidal in the lower ileum without unfavorably affecting the jejunal mucosa? Would not any unabsorbed phenol be reduced to the relatively inocuous albuminate? And yet theoretically there may be some substance capable of inhibiting typhoid bacteria without at the same time being injudious to the bowel or system.

The use of turpentine for meteorism has widespread clinical support, though the way in which turpentine can thus be of benefit has not been explained. Most of the essential oils mildly stimulate peristalsis through local irritation, but they seem to possess some other property not common to other exciters of peristalsis. The control of undue flatulency, as well as of diarrheic disturbances, may also be attempted by alterations of diet, increasing the allotment of pancreatinized foods and meat essences, and decreasing starches and fats.

Acetphenetidin is sometimes temporarily desirable for the treatment of the severe initial headache which usually characterizes typhoid, but when employing this drug we must bear in mind that it is simply an interpreter of pain sensations, and is to be used when simpler measures, like complete rest and local applications of the ice bag, fail to give relief.

Epinephrine is spoken of in a recent text as serviceable in case of hemorrhage in typhoid; but to the pharmacologist epinephrine seems to be contraindicated, inasmuch as it raises blood pressure enormously, has little or no constrictor effect on distant oozing bloodvessels except when used intravenously and not always then, and at its best it transitory in its action. When hemorrhage cannot be controlled by quiet and the lessening of peristalsis, operative procedures should be resorted to, intermediate support being obtained by repeated enemata of warm saline solution.

If alcohol is ever useful as a medicine, it may be considered of value in the low stages of typhoid when its oxidation may help to conserve the body tissues; but whether it may not do more harm than good under these conditions remains a debatable question.

Treatment of Neuralgia and Rheumatism.—C. Ziemann (*Journal of the Medical Society of New Jersey*, July, 1916).

℞ Tincture of iodine, ...3i;
Gum camphor, ...3i;
Chloroform, q. s. ad.....3v.
M. Sig. Apply as directed.

Operative Treatment of Infantile Paralysis.—Mark H. Rogers (*American Journal of Orthopedic Surgery*, July, 1916) reports the operative results in 130 cases of infantile paralysis, the work having been done by the orthopedic staff of the Massachusetts General Hospital. He finds that, in children when deformities are not developing, the fewer the operations performed the better; that, in adults, good results are obtained by tendon transplantation with and without bony resection; and that astragalectomy is preferable to arthrodesis of the ankle joint in cases presenting deformity.

Operative Treatment for the Disabilities and Deformities Following Anterior Poliomyelitis, as Practised at the Hospital for Ruptured and Crippled.—Charlton Wallace (*American Journal of Orthopedic Surgery*, July, 1916) reports success with the Soutter and Whitman operations, the transplantation of the hamstrings for quadriceps paralysis, and the grooving of the tibialis anticus and transplantation of the extensor proprius hallucis into the calcaneoscaphoid ligament for equinovalgus. He reports poor results with arthrodesis in children. He believes that many operations would be unnecessary if the proper brace treatment was instituted.

Operative Treatment of Infantile Paralysis.—R. Tunstall Taylor (*American Journal of Orthopedic Surgery*, July, 1916) believes that tenotomy, myotomy, and tendon lengthening should be performed only if a transplantation cannot be done; that tendon shortening is successful if the tendon is anchored in a periosteal or bone groove; tenodesis is justifiable when the muscle of the tendon has degenerated beyond functional use; extraarticular and intraarticular silk ligaments should be preferred in flail joints where no impotent tendons are obtainable for a tenodesis; arthrodesis should be used only in flail joints and not preferred to tenodesis and extraarticular silk ligaments; articular transplantation for calcaneus gives no increase in power of extension unless a tendon transplantation accompanies the operation; astragalectomy should be used only when other methods fail; and tendon transplantation is probably most successful in partially paralyzed cases.

Treatment of Summer Complaint Among Children.—R. C. Youngblood (*Texas Medical Journal*, July, 1916) divides the treatment into dietetic and medicinal. Breast milk is the ideal food for infants. As a substitute, condensed milk may be used. Barley water, rice water, oatmeal gruel, and occasionally, orange or beef juice should be added. For the medicinal treatment, summer complaints among children are divided into two groups: Gastroenteritis (cholera infantum) and ileocolitis. In gastroenteritis, morphine sulphate, grain 1/50, strychnine, grain 1/250, and atropine, grain 1/1000, repeated in two hours if necessary, should be administered. If there is improvement, we give one tenth or one sixth of a grain of calomel every half hour for six doses, followed by two teaspoonfuls of castor oil; later, zinc sulphocarbolate in one sixth to two grain doses every two hours until convalescence is well under way. In treating ileocolitis we use calomel and castor oil, as stated above. If the fever reaches 102.5 F. again, another dose of castor oil is indicated. Where there is mucus, blood, and dark green stools bismuth subnitrate is of immense value. The dose is ten to twenty grains every two hours. If black stools do not appear in twenty-four hours, add precipitated sulphur, one grain, to every dose. For the tenesmus we exhibit paregoric and enemas of normal salt solution and starch; in the presence of high fever, colonic irrigations with normal salt solution.

Treatment of Vesicular Eczema.—P. G. Unna (*Berlin. klin. Woch.*, January 10, 1916) states that, although lead water gives pleasant relief to itching, it is not a useful treatment, for it often increases the eczema through too great maceration of the tissues. The same is true of aluminum acetate solution. More satisfactory are ice bags for symptomatic relief, combined with the direct application of zinc sulphurata paste, which is covered with a mull bandage to be kept moist with aluminum acetate solution or sterile water. The paste abstracts water from the eczema, and the moist dressing reduces the hyperemia through the cooling of evaporation. In place of this form of dressing we may use a cooling paste, made according to either of the following formulæ:

℞ Magnesii carbonatis, ...10 grams;
Liquoris plumbi acetatis, ...50 grams;
M. et adde unguenti zinci oxidi, ...40 grams.

℞ Pulveris ichthargani, ...20 grams;[1]
Liquoris alumini acetatis, ...40 grams;
M. et adde eucerini, ...40 grams.

Choral Hydrate in Cardiovascular Affections.—A. Martinet (*Presse médicale*, June 5, 1916) points out that the warning against the use of chloral hydrate in cardiovascular disorders given in numerous textbooks is unwarranted and has done harm in preventing the employment for hypotensor purposes of a drug both more efficacious and less injurious than the nitrites. Impressions concerning the action of chloral on the heart have been derived chiefly from intravenous injection of toxic doses in animals. Actually, depression of the myocardium does not occur until enough has been given to depress dangerously the respiratory centres and the centres of nervous cardiac regulation. Daily doses of twenty-eight grams of chloral have in a number of instances been given to tetanus patients without harm to the circulation. In dogs no increase of tolerance of the drug develops from its daily administration, even for long periods. The chronic toxic effects of chloral are exerted chiefly on the nerve centres, including especially the vasomotor centres, and to no special extent on the heart. Clinically, chloral is, with bromides, one of the best relievers of general and circulatory spasm. Many cases of angiospasm and high blood pressure attacks, with or without sleeplessness, are effectually allayed. As advised by Brunton chloralized patients, when marked vasodilatation and heat loss result, should be kept warm with flannel and hot water bags. Another most useful property is that of improving the urinary outflow where oliguria, combined with insomnia and high blood pressure, seems due to excessive nervous

[1]Pulvis ichthargani has the following composition:
℞ Ichthargani ..... 1 gram;
Magnesii carbonatis..... 20 grams.

excitability causing excessive renal vasoconstriction. In well compensated high pressure cases with a urinary output of one fourth to one third litre in sixteen to eighteen hours, sleep induced by chloral hydrate is characteristically followed on awakening by an abundant diuresis, as much as a litre of urine being passed in six or eight hours, with manifest euphoria, relaxation from nervous tension, and lessened difficulty of breathing. The drop produced in the systolic blood pressure, which may attain thirty or forty mm., is coupled with a corresponding fall in the diastolic, thus clearly betokening a peripheral as well as renal vasodilatation. Where caffeine, used as a diuretic, has been given in doses so large as to cause constriction of the renal vessels and arrest the flow of urine (especially in excitable subjects), a small dose of chloral suffices to overcome the inhibiting angiospasm and produce diuresis. Chloral and caffeine make sometimes the combination of choice for diuretic purposes. While thus clearly indicated in conditions of neurocardiovascular erethism with insomnia, high blood pressure, and oliguria, chloral is, on the other hand, contraindicated in neurocardiovascular asthenia, low pressure, and somnolence, with or without reduced urinary output.

Acute Gonorrhea.—F. L. Ashton (*Northwest Medicine*, June, 1916) avers that this common infection is frequently mismanaged. Each case should be treated individually according to indications. No local treatment should be employed in the acute stage, but more attention should be devoted to the use of internal medication, diet, and general hygiene. At this stage, unless there is some contraindication, five to ten minims of oil of sandal wood should be given hourly until pain on micturition is controlled. Only after the local inflammation has subsided somewhat should local treatment by injection be begun. It is a mistake to pin one's faith on any single drug, for a given patient may not respond to a drug which gave prompt results in another, while a change to some other drug will give the best of results. It is fallacious to try to cure posterior urethritis with prostatic and seminal involvement by internal remedies alone, and in such cases there should be systematic massage.

Treatment of Auricular Fibrillation.—Robert H. Babcock (*Medical Herald*, June, 1916) says there are four essentials to be considered, namely, rest in bed, the relief of insomnia and dyspnea, reduction of visceral congestions, and slowing and stimulation of the heart. For the insomnia a hypodermic injection of morphine or other opiate is the best remedy, milder hypnotics such as bromides, hydrated chloral, etc., seldom sufficing. The dose of morphine should be large enough to insure a comfortable night and should be repeated nightly in decreasing doses so long as the insomnia and dyspnea continue. If morphine is not well tolerated, heroine or codeine may be substituted. Vigorous purgation is always needed, but if an opiate is being used its need is even more imperative. Five to ten grains of blue mass with half a grain of extract of hyoscyamus is satisfactory, followed in the morning by a saline cathartic to which a dram of bicarbonate of sodium has been added. The daily use of an alkaline saline laxative should be continued as long as there is visceral congestion. For the slowing and stimulation of the heart, digitalis in some form is the only drug; it should be given in the form of strophanthine intravenously in doses of half to one mgm. repeated not oftener than once every twenty-four hours. The digitalis medication should be continued until there has been marked slowing, after which it will be necessary to find a dose for each patient which will be just enough to hold the heart at a good level of efficiency; he should continue to take this dose the rest of his life. He should always be kept under observation to prevent the return of broken compensation, and when the premonitory signs are seen, the treatment outlined should be begun at once.

Some Indications for Venesection.—A. Theilhaber (*Berlin. klin. Woch.*, January 10, 1916) believes that this therapeutic measure is too little appreciated. It gives great relief in many conditions, such as dysmenorrhea, intermenstrual colic, the symptoms of the menopause, neuralgias and neuroses in plethoric persons, and some forms of nervous headache. There is, however, another field in which venesection is valuable, namely, as a means of minimizing the recurrence of cancer after operation. Whether the original cancer has been wholly removed or not, the withdrawal of 400 to 500 c. c. of blood twice each year will accomplish much in preventing recurrence or metastases. The mechanism is believed to be dependent upon the stimulation of the hematopoietic organs secondary to the removal of the blood. If this practice is combined with diathermy and glandular extracts, excellent results may be expected.

The Rapid Treatment of Epithelioma and Lupus.—C. S. Neiswanger (*Chicago Med. Recorder*, June, 1916) states that the method depends upon zinc cataphoresis adequately carried out. The surface of the lesion should be cleansed with hydrogen peroxide or boric acid solution and over it a suitable pledget of cotton saturated with a ten per cent. solution of cocaine should be laid. Using a block tin electrode attached to the anode a constant current of five to ten milliampères is turned on through the cocaine and maintained for about five minutes or until there is complete anesthesia. It is best to wind the cotton pledget about the anode. This is then squeezed dry of cocaine and wet with a saturated solution of zinc sulphate and reapplied. Cataphoresis with a current of the same strength as previously employed should then be carried out until every portion of the ulcerating surface has become blanched. It is not necessary to observe great care to protect the sound tissues about the ulcer. A day or two after such a treatment the surface of the ulcer will have turned black and the crust may be removed after the fourth day, leaving a healthy cicatrix. If after several weeks any small nodules reappear they should at once be treated as originally. In the majority of cases, if the first application has been thorough, no repetition will be required. Some scarring always follows the treatment, as all three layers of the skin are involved.

Removal of Adenoid Growths.—J. L. Aymard (*Lancet*, June 24, 1916) considers that accurate diagnosis of the presence, size, shape and precise location of these growths cannot be made without direct inspection of the affected region, aided by a specially devised tongue depressor and a suitable palatine retractor. The same is true of their removal. The author discusses the reasons for the inadequacy of the curettes in common use and describes a pair of specially shaped scissors and a pair of similarly constructed clamps, by which it is possible to remove completely all of the pathological tissues without the risk of damage to adjacent parts. The removal should be done leisurely, with good view of the operative field and under a moderate degree of general anesthesia. Prior to their removal, which should always precede the removal of hypertrophied tonsils, there should be some toilet of the nasal passages and throat. Cleansing is probably best accomplished by the use of peroxide of hydrogen. Following the operation we should be sure that all hemorrhage is checked, and to reduce the danger of late hemorrhage the use of adrenaline should be abandoned.

Venereal Disease in European Armies.—E. Kilbourne Tullidge (*Military Surgeon*, July, 1916) says the various treatments for the respective venereal diseases are familiar to all members of the profession, and therefore need no elaboration. He consequently mentions only a novel and excellent treatment for venereal bubo or inguinal adenitis practised in the field where it was discovered accidentally by a German officer in charge of a mobile Röntgen apparatus. He treated the partly inflamed swelling symptomatically with röntgenotherapy (10-20x with a 0.5 mm. aluminum filter) with the result that in a short time fluctuation, pain, redness, and swelling gradually disappeared and the retrogressive changes that followed left only a small pigmented spot or scar.

Second Thoughts about Salvarsan Therapy.—William E. Stevens (*Caliornia State Journal of Medicine*, July, 1916) presents us with the following list of "Don'ts." Don't use salvarsan unless positive indications for its employment exist. Don't expect as much from neosalvarsan as from salvarsan. Don't give salvarsan in the office. Don't give salvarsan at too frequent intervals, or in too small doses. Don't omit any details in preparing the solution to be injected. Don't neglect to filter the solution before it is injected. Don't cut down on a vein. Don't inject any of the solution into the tissues surrounding the vein. Don't administer too large a dose at the first injection, especially in the early secondary stages. Don't inject salvarsanized serum prepared from a Wassermann positive blood into a canal containing Wassermann negative fluid. Don't inject air into the spinal canal. Don't use intradural medication under any circumstances until the intensive treatment with intravenous injections of salvarsan, mercury inunctions or injections, and potassium iodide has been given a thorough trial. Preliminary medication is of the highest importance in securing the most satisfaction in comfort to the patient and in attaining complete anesthesia without danger. Three doses of morphine given at three quarters of an hour intervals should render the patient distinctly drowsy when he comes to the operating room, and the size of the dose must be determined by watching the effect of the first and second injections. The use of scopolamine is not necessary and adds to the risk, which is decreased by morphine alone. The use of local with the general anesthesia is likewise of great assistance. Gas and oxygen anesthesia is indicated in all cases of obvious lung irritation, when there is reason to think that there is a latent lung process, and when the kidneys are severely damaged. Stevens believes it to be the safest anesthetic in old men with weak lungs and atheromatous bloodvessels, if there is any marked kidney damage, and with increasing skill in administration it may become the safest under any condition. Spinal anesthesia is of more limited use, as it cannot safely be used above the level of the pelvis. The great advantage is that all stimuli to the brain are cut off and shock much lessened, but the mortality has been high. A skilled man is needed to administer it, and the psychic shock may be considerable. In a limited field it is very valuable. In cases of great vesical irritability needing cystoscopy the paralysis of the motor nerves allows of the maximum dilatation with safety as well as without sensation. It is useful also in perineal prostatectomies, and amputations of the legs for gangrene in diabetes. Local anesthesia has gained in importance since the introduction of novocaine, and as our skill increases the class of cases in which this is the preferable method grows larger, but the psychic effects on the conscious patients must be borne in mind. It is indicated today in all operations on the scrotum or its contents, and in minor operations generally.

Aftertreatment of Colles's Fracture.—J. A. Arnold (*American Journal of Surgery*, July, 1916) says that the aftertreatment of a Colles's fracture, for at least eight or ten days, is the same as the first, except inspection and instruction to the patient to cut the bandage at any time it should become too tight, in the event that he cannot reach his physician. It is preferable to take the risk of having to reset the arm than to have a myositis with its subsequent contractions, and this condition will manifest itself within the first twenty-four to thirty-six hours. Otherwise, in the aftertreatment, the splints should remain as applied without interference, unless swelling or other pressure symptoms arise to necessitate changing. After the first ten days remove the splints and make slight movement, which should be repeated at intervals of two or three days. Take the anterior splint off, and use only the one dorsal splint. The anterior splint should never be used except in conjunction with the dorsal, as it will not only fail to correct a deformity, but will produce one in an otherwise perfectly reduced fracture. Keep the dorsal splints on, as an average, in the case of a young person, about three weeks; in the case of an old person, about four weeks; then remove all dressings, except perhaps adhesive plaster to support the wrist, and practise passive motion.

Tuberculin Therapy: Its Principles, Limitations, and Indications.—Walter C. Klotz (*California State Journal of Medicine,* July, 1916) says that on a pathological basis our knowledge of tuberculin is limited to the phenomenon of the focal reaction, which is the essential feature of the tuberculin reaction. The basis for indications and contraindications for tuberculin therapy is an estimation of the degree of reactivity of the tissues at the site of the tuberculous lesions. This can be determined only by a careful clinical study of each case. The principal object of tuberculin therapy is to establish tuberculin tolerance, which is not permanent, and the protection offered by it is limited. The various biological tests are too variable to serve as safe guide for doses in tuberculin therapy. The dose is not and cannot be absolute, but must be determined for each individual case, according to the clinical picture.

Desirability of Using Miotics as Adjuvants to Mydriatics.—Harold Gifford (*Jour. A. M. A.*, July 8, 1916) reports five cases in which glaucoma followed the instillation of small amounts of homatropine into the eyes for the purposes of refraction. A review of the literature shows this occurrence to be rare—not over once in 10,000 cases—but steps should always be taken to prevent its development. Three of the five cases suffered permanent damage to vision, while the other two were cured by the immediate use of physostigmine instillations. On the strength of the author's experiences it is urged that physostigmine should be used as a routine following the employment of such mydriatics as homatropine. The only exception to this rule is in the case of young children. For every patient who has had homatropine for any ophthalmological purpose, there should be prescribed ten or fifteen drops of a solution containing one grain of physostigmine to the ounce. The patient should be directed to use one drop, three times daily, until the pupil has returned to normal and the sight for near objects is restored. It is also recommended that the home instillation be made from the tip of a toothpick or a match to avoid too large a dose. This prescription should be given in addition to the immediate instillation of the same drug in the office. The need for the continued use of the miotic arises from the fact that the action of the homatropine often persists for some time and because some of the cases of glaucoma resulting from its use have first developed many hours after its administration.

Regeneration of Bone.—Franklin D. Smith (*American Journal of the Medical Sciences*, July, 1916) tells us that osteogenesis is not a specific attribute of any tissue or layer of cells, but is limited entirely to the osteoblasts which are scattered throughout the entire structure. Mature bone cells are end products, and while they may undergo mitosis under artificial conditions, this process is unknown in the human economy. Many mature bone cells of a transplant remain alive, especially near the periphery of the transplant, and control its calcified matrix. Absorption of isobone is influenced in many cases by the treatment received by the transplant. Protoplasmic poisons should not be employed during bone grafting procedures. Regeneration of bone for the most part is an indirect process through the differentiation of the osteoblast to a mature bone cell. A transplant is subject to the varying demands of its environment; functional demands producing an increase in bone deposition, while lack of functional demands causes atrophy and absorption. Bony contact is not essential to regeneration of bone, but for practical purposes, doubly insures the result desired. In the transplantation of any bone the most that can be hoped for is the continued development of the implanted osteoblasts, together with such stimulus as may be obtained from the osteoblasts of the host and the retention of vitality in some of the transplanted bone cells with their corresponding intercellular calcium matrix. The transplant in the presence of an infection may or may not survive, and is dependent on the type of the infecting agent. The medullary transplant is not a permanent entity, but is absorbed as soon as all functional demands are removed.

Anesthesia.—Edward L. Young, Jr. (*Boston Medical and Surgical Journal,* July 6, 1916) says that because of its low mortality and very wide margin of safety, ether is the anesthetic of election in the majority of routine surgical cases. Preliminary medication with a hypodermic injection of morphine and atropine helps to quieter and more rapid induction of unconsciousness. The use of gas to put the patient to sleep and then the substitution of ether is much easier for the patient, and in so far as it lessens the stage of excitement and the amount of ether used, is likewise safer. A certain amount of rebreathing is probably necessary to preserve the gas balance in the blood, and this is one of the advantages of the drop method of administration, just enough rebreathing goes on, and there is not, as in most closed cones, far too much, as well as periods of too great ether concentration. The clinical fact seems to be beyond dispute that when a local as well as a general anesthetic is used, patients are better relaxed with less ether, there is less shock from the operation, and the postoperative course is much smoother. Nitrous oxide gas may be used for all minor operations requiring but a short time, and in such operations it is by far the safest anesthetic. Mixed with about eight per cent. of oxygen to prevent cyanosis, gas may be used for operations of any duration in the majority of patients. This mixture is not irritating to the lungs or kidneys; has no bad effect on the heart when properly administered, unless the patient is unfit; tends to raise the blood pressure slightly except at the end of long operations; is easy to take, and recovery is quick with few if any symptoms; but the margin of safety is narrow. The immediate mortality from its administration varies with the skill with which it is given. In the hands of experts it is safe, but in the hands of the inexperienced or careless the mortality is believed to be higher than that of any other anesthetic in general use. The minute any cyanosis develops the danger zone is in sight; the face should remain of a pink color. When a patient cannot be anesthetized satisfactorily without cyanosis, gas and oxygen alone should not be employed.

Miscellany from Home and Foreign Journals

An Unusual Epidemic of Whooping Cough.—P. Tissier (*Bulletin de l'Académie de médecine*, June 6, 1916) writes concerning the whooping cough epidemic which prevailed in Paris and its outskirts from April to July, 1915, and from December, 1915, to the time of publication. Of 144 cases treated by the author no fewer than ninety-four were in adults. The cases occurring in children were often contracted from the parents. Though not, as a rule, immediately grave, the disease, in adults, ran a protracted and tedious course and was fraught with serious consequences, especially in the aged, in those already afflicted with bronchopulmonary or cardiac disease, and in soldiers infected while on a furlough and later transmitting the disease afar. The condition being mild at the outset, the adult patients often failed to interrupt, or left off only a few days, their customary occupations. The majority of cases seen had already been diagnosed as grippe, nervous cough, tonsil cough, or reflex spasmodic cough. The actual nature of the condition was shown, however, by the paroxysmal cough, frequently with nausea and at times vomiting, the absence of bronchial disturbance, and of marked involvement of the upper respiratory passages, the ready yielding of the condition to the ordinary treatment for pertussis while refractory to that for grippe or bronchitis, and especially, its contagiousness. The pertussis contracted by children from their parents was always typical and generally severe. The disease in adults constantly began with slight coryza, sore throat, or hoarseness, followed later by dry, paroxysmal cough, seldom with expectoration, which consisted of saliva alone. All the patients experienced a tickling sensation in the throat which obliged them to cough. The paroxysms then became more and more frequent, though the cough remained dry and was not, as in children, accompanied by suffocating attacks. Treatment with bromoform, chloroform, iodoform, or fluoroform proved effectual, early administration being, however, necessary to ward off bronchopulmonary complications, against which these remedies are powerless.

Infectiousness of the Cerebrospinal Fluid in Syphilis.—Richard Frühwald and Alexander Zaloziecki (*Berlin. klin. Woch.*, January 3, 1916) inoculated spinal fluid from twenty-three cases of syphilis in various stages of the disease into the testicles of rabbits to determine the infectiousness of the fluid in the several stages. The authors summarize the result of all positive cases in the literature to date as follows. Acquired syphilis: A. Without objective nervous symptoms, no positive result before the eighth week of the disease; two positive cases in the eighth to tenth weeks, during the primary and secondary stage; in older secondary cases of three to twelve months' duration, seven positives; no positive result in tertiary syphilis. B. In cases with objective nervous symptoms—one case of early meningitis gave a positive result and one of neural recurrence; two positives in hemiplegia and apoplexy; one in a syphilitic meningitis of unknown duration; one in spinal syphilis; and, in metasyphilis, there were two positive results in tabes and five in progressive paralysis. Hereditary syphilis: Two positive cases in newborn infants without symptoms referable to central nervous involvement, and two in older cases of inherited syphilis. One of the most striking features of these findings is that in the secondary stage, where the positive results are most frequent, these results bear no necessary relation to the condition of the spinal fluid, which may or may not be pathological, and may or may not give a positive Wassermann reaction. In all cases, however, the Wassermann reaction in the blood was positive. Another striking fact was the absence of positive findings in the tertiary stage of syphilis.

Etiology of Cancer of the Esophagus and Stomach.—William Lerche (*Surgery, Gynecology, and Obstetrics*, July, 1916) summarizes the question of cancer of the esophagus and stomach as follows: 1. Cancer of the esophagus is exceedingly rare in animals. 2. Cancer of the stomach is rare in animals. 3. Cancer of the esophagus and stomach is comparatively rare in the natives of tropical and subtropical countries. 4. Cancer of the esophagus and stomach is common in certain countries in the temperate zones. 5. Cancer of the esophagus is much more frequent in men than in women. 6. Cancer of the stomach occurs with almost equal frequency in both sexes. 7. Cicatricial strictures of the esophagus and the stomach from swallowed corrosive fluids particularly, form at certain parts of these organs and for definite physiological reasons. 8. The favorite sites of cancer in the esophagus and in the stomach correspond exactly to the favorite sites of the cicatricial strictures in these organs.

Relapsing Fever.—Frederic Hagler (*Military Surgeon*, July, 1916) states that much may be said as to the importance of the role of the body louse in the transmission of relapsing fever. In Serbia, relapsing fever appeared with typhus fever (which is admittedly transmitted by the louse), and measures instituted against lice soon markedly decreased the incidence of each. This difference is noted, however, that whereas typhus practically disappeared with the lice, relapsing fever persisted and continued to develop in the medical wards of the Belgrade hospital until systematic sulphurous fumigation of wards and rooms was undertaken to destroy bedbugs. After this it also disappeared. Thus it would seem that the bedbug certainly is one and probably the most common of the agents of transmission. A further significant fact is this: Of approximately fifty Red Cross surgeons and nurses assigned to Serbia, at least twenty contracted typhus, while in none relapsing fever developed. If the methods of transmission were the same we should expect at least a few cases of relapsing fever to have arisen among this number, and, in view of the lesser likelihood of nurses and physicians being bitten by bedbugs than by lice, it seems probable that the bedbug plays a larger part in the transmission than is generally ascribed to it.

Trophic Disturbances Following Superficial Wounds.—Mouchet and Poirot-Delpech (*Paris médical*, May 27, 1916) record an instance of curious trophic changes in the ring and little fingers of the left hand, following a superficial wound by shell fragments on the ulnar side of the dorsum of this hand. The two fingers referred to are practically reduced to bone and skin, the latter being reddish and squamous throughout. The nails are markedly striated and curved. The two fingers remain extended and somewhat divergent, flexor power being practically lost, though careful palpation reveals no impairment of the flexor or extensor tendons. Sensation in the fingers is diminished, but the fingers are sensitive to cold, becoming purplish as soon as the atmospheric temperature falls. There is no traumatic lesion of the metacarpals or the corresponding interosseous and lumbricalis muscles. Röntgen ray examination, however, reveals an osteoporosis of the last two metacarpals and the phalangeal bones. The ulnar nerve shows normal electric reactions except at the wrist, where no reaction is obtainable. The condition has been treated for some time with massage, hot air, and hot running water, without result.

Mycetoma in Hawaii.—M. T. Clegg and W. C. Hobdy (*American Journal of Tropical Diseases and Preventive Medicine*, April, 1916) report a case of Madura foot in a native Hawaiian fisherwoman, the condition having begun over five years previously after a puncture of the sole of the foot on a coral reef. After four years sinuses had begun to form on the dorsum of the foot, and the patient's general health was impaired. The foot attained nearly twice the normal size. Treatment consisted in amputation six inches above the upper margin of the diseased tissue, and was completely successful, without recurrence. That more than one species of streptothrix may cause Madura foot has been fully established. From this case cultures of an organism identical with that isolated by Vincent in India, Streptothrix maduræ Vincent, were obtained.

Some Bodily Changes during Anesthesia.—Frank C. Mann (*Journal A. M. A.*, July 15, 1916) made experimental studies on dogs, and attempted to eliminate changes due to struggling, excitement, and asphyxia. The blood was the chief subject of investigation and its volume was found to undergo about ten per cent. reduction after six to nine hours of light etherization. Since lecithin is greatly increased in the blood during anesthesia, studies were made of the cholesterin and yielded such variable results that no uniform response could be determined. There seemed, however, to be some increase in this lipoid also. No change occurred in the specific gravity of the blood under light anesthesia and none even when the anesthesia was deep until asphyxia developed. No alteration in the number or fragility of the red cells or in the amount of hemoglobin occurred. A constant change did appear in the number of the white cells, which varied from a slight increase to over twice the normal number. This increase was usually present after two or three hours of etherization and was due chiefly to an increase in the polymorphonuclear elements; the change was independent of the spleen and was not influenced by atropine. It is probably due to some direct effect on the bone marrow. Using a new method, consisting of injecting known suspensions of bacteria into a doubly ligated portion of vein and incubating in the living animal, it was determined that etherization for five or six hours did not depress phagocytosis.

Intraventricular Cerebral Hemorrhage.—Alfred Gordon (*Archives of Internal Medicine*, March, 1916), from a study of five personal cases of primary intraventricular hemorrhage—two into both lateral ventricles and three into a single lateral ventricle—is led to consider a sudden onset without premonitory symptoms, profound coma continuing several days without improvement, absence of marked paralysis, absence of rigidity and contracture in the days following the seizure, and absence of the toe phenomenon, as indicative of this relatively uncommon form of cerebral hemorrhage. Early surgical decompression on the sound side is advised, the profound coma being, perhaps, due to sudden compression of the normal brain tissue on this side by the hemorrhagic effusion on the other. In one of Gordon's cases this procedure was followed on the fifth day, and in spite of the delay distinct amelioration resulted.

Simple Tic Mechanism.—C. P. Oberndorf (*Jour. A. M. A.*, July 8, 1916) reports three cases of tic to show that the probable mechanism of this phenomenon is a simple one, referable to an interaction of a mental censor and a primary autopleasurable act. Thus in one instance the tic consisted of pressing the extended thumb deeply into one cheek. This was traced back to the childhood habit of sucking the thumb—an act of autoerotism, hence one of pleasure. The form of the tic as it was encountered was due to the modification demanded by the individual's mental censor. Psychanalysis led to the disappearance of the tics in all three cases, owing rather to the solution of more vexing problems which troubled the patients than to the direct effect of the analysis.

Right Side of the Heart in Relation to Overstrain.—William Russell (*Brit. Med. Jour.*, June 24, 1916) considers that more attention should be paid to the condition of the right side of the heart, for it can give valuable evidence of changes occurring in the left heart as well. Visible pulsation over the body of the heart is due to the right ventricle and may be referable either to its dilatation or to the heart being pushed close to the chest wall by an enlarged left ventricle. The latter is the more common cause, since the right ventricle is not easily dilated. The pulmonary second sound, when accentuated, is evidence of some degree of impairment of the power of the left ventricle leading to a damming back of the blood into the lesser circuit. The occurrence of a systolic murmur in the pulmonary artery also reflects upon the condition of the left ventricle, for its mechanism is probably secondary to a narrowing of this vessel through enlargement of the left ventricle and a kinking of the origin of the vessel. It is a murmur stictly functional in origin, although usually significant of some organic lesion of the left side of the heart. The absence of the

first sound heard over the right ventricle indicates weakness of that chamber, and is common in cases with fatty infiltration. Sudden death is a frequent termination in such cases. Pulmonary diastolic murmurs are almost invariably due to endocarditis in that region or are secondary to more or less failure of the left side.

Prostatic Nodes; Their Significance.—Noah E. Aronstam (*American Journal of Surgery,* June, 1916) thus summarizes his views on this question. 1. Gonorrhea is the most common cause of prostatic nodes. 2. By reason of the nodes the prostate is altered both structurally and functionally. 3. The prostatic secretion produced under these circumstances is no longer a normal and physiological secretion. 4. As such it can no longer activate the spermatic fluid. The normal prostatic secretion exerts a powerful influence upon virility, and if pathologically altered may thus cause partial or complete impotence. 5. The prostatic nodes are sources of toxin absorption and are responsible for the subsequent train of symptoms thus engendered. 6. Treatment is unsatisfactory and problematical.

Complete Congenital Atresia of the Ileum.—This case is reported by Royale H. Fowler (*Medical Record,* June 10, 1916), as the first of the kind to be recorded. The ileum ended in a blind pouch twenty-two and a half inches from the ileocecal valve, and the whole small intestine measured only fifty-six inches in length, which is only one half the normal length.

Life History of Ascaris lumbricoides.—F. H. Stewart (*Brit. Med. Jour.,* July 1, 1916) did experiments which showed that pigs could not be infected with the parasite, but that white rats were susceptible. The eggs passed by man developed into mature embryos in the presence of moisture and at a temperature ranging from 25° to 30° C. If such eggs reach the intestinal tract of the rat, they hatch and the liberated larvæ enter the body of the host, being found in the bloodvessels, liver, spleen, and lungs after four to six days. On and after the sixth day they have all passed into the air cells of the lungs, where they produce hemorrhagic inflammation and render the host very sick. After the tenth day no larvæ can be found except in the lungs. If the attack is not fatal, the host is free from parasites by the sixteenth day. Evidently there is an alteration of hosts; the experiments do not prove, however, that the rat is the natural or the only intermediate host.

Diagnosis of Cancer of the Stomach.—James Alexander Lindsay (*Lancet,* July 1, 1916) thinks it a simple matter to make a correct diagnosis of this disease in the later stages, but it is more important and difficult to make the diagnosis in the early stages. The condition was found to be most frequent in the fifth to seventh decades, being rare below thirty years; there was a clear family history in about ten per cent. of the cases; and a history of previous gastric ulcer in only 12.5 per cent. The mode of onset was found to be of importance from a diagnostic viewpoint, the signal symptom having been, in order of frequency: Painful dyspepsia, vomiting and pyrosis, loss of weight, progressive weakness and anemia; hematemesis, anorexia, and melena. In nearly half of the cases fever was noted, seldom above 102° F. Usually one of the signal symptoms will be found to develop abruptly in a person over forty years of age who had previously been in good health. One or more of the remaining symptoms mentioned as signal symptoms will sooner or later appear, particularly loss of weight, anorexia, and vomiting. Such a picture suggests early examination of the gastric contents.

The Factor of Fear in Nervous Cases.—Hugh T. Patrick (*Journal A. M. A.,* July 15, 1916) says it is well known that fear is a factor in many cases of functional nervous disorder, but he contends that this emotion is at the bottom of a large number of other cases in which its presence is not commonly recognized. He presents brief histories of a number of cases which illustrate how common and potent a cause of functional, mental, and even somatic phenomena fear actually is. Many of the patients whose cases are cited were persons of unusual bravery, yet they were the victims of fears which caused them much suffering.

Systolic Pressure in Acute Nephritis.—Rodolph G. Abercrombie (*Brit. Med. Jour.,* June 24, 1916) reports observations made on several hundred cases of acute nephritis. It was found that the systolic blood pressure was always raised some time in the course of the disease, but not to so great a degree as in chronic nephritis. A striking feature of the systolic pressure was found to be the occurrence of wide diurnal variations, the highest point being in the evening. Often as recovery progressed the elevated pressure fell *pari passu* with the clinical improvement. In cases with uremic convulsions, the pressure averaged much higher than in the nonuremic cases, although in some it remained persistently low.

Branchiogenic Carcinoma.—Frank Warner (*Annals of Surgery,* July 1916) concludes: 1. The mortality of branchiogenic carcinomata is very high. This is probably due as much to the start it gets before operations, owing to its deep seat, rendering diagnosis difficult, as to extreme malignancy of the growth, although this is sometimes great. 2. In rapidly growing branchiogenic carcinomata, the cell differentiation may be so imperfect in many fields as to simulate tumors of endothelial origin; other fields usually clear up this uncertainty. 3. Operations for the relief of branchiogenic carcinomata are always serious, owing to their attachment to deeper structures which may require removal. Both the carotid artery and jugular vein may be injured to an extent requiring the removal of a section: the pneumogastric nerve may be injured at the same time. 4. The only hope for making any satisfactory reduction in the mortality rate following operations for branchiogenic carcinomata is to operate earlier in their progress. 5. Any hard swelling in the region of the branchiogenic clefts should immediately arouse suspicion of branchiogenic carcinoma, especially if associated with pain as a prominent symptom.

Proceedings of National and Local Societies

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Joint Meeting Held July 13, 1916, at 8:30 p. m., under the Auspices of the Department of Public Health and Charities of Philadelphia, The Philadelphia County Medical Society, and the Philadelphia Pediatric Society, to Discuss Anterior Poliomyelitis.

Dr. JOHN D. MCLEAN, President, Philadelphia County Medical Society, in the Chair.

Infantile Spinal Paralysis.—Dr. CHARLES K. MILLS said that experience with this disease pointed to the fact that the malady was infectious or microbic in origin and tended to spread by at least two methods, through certain occult atmospheric or climatic influences, and by contagion. The healthy children of a family should be removed to other neighborhoods and the sick quarantined. Through the work of Flexner and others the measures were known which should be taken to prevent the spread of the disease by the secretions of the nasopharynx and the intestinal excretions. Good nursing played a large role in the treatment of infantile paralysis in all periods of the disease. Rest of the body and mind was said to be in the highest degree important. The virtue of a quiet and composed manner should be remembered by the nurse and enforced by the physician. Light and sound should be excluded during the acute febrile stage; also insect life. The closest attention should be paid to keeping clean the nose and throat by gentle spraying with solutions of hydrogen peroxide or other germicidal solutions. Attention should also be paid to the intestinal excretions. With the appearance of paralysis and contractures the limbs should be kept in positions less liable to lead to subsequent deformities. Massage should not be used until the fever had largely disappeared; at first it should be employed simply as a gentle stroking: later there should be moderate kneading combined with the stroking. Instead of the patient being lifted out of the bed, the position should be changed in the bed. A typical case of the disease was easy of recognition within three or four days after the onset of fever. It should be suspected before the paresis appeared. The presence or absence of pain and hyperesthesia might be of value in determining whether or not the lesion was closely limited to the spinal cord or higher regions of the neuraxis or whether meningeal implications were shown. The physician should not make the mistake of supposing he was dealing with simple meningitis or neuritis when the fundamental disorder was poliomyelitis. In a neighboring epidemic of poliomyelitis one of the most essential things to remember was the frequent existence of abortive and aberrant cases, so atypical that their nature was doubtful. Such cases were as much a source of danger to the uninfected as those fully developed. As a neurologist Doctor Mill's attention had been called in a striking manner to mistakes in diagnosis in severe cases of poliomyelitis, especially those showing bulbar, cerebellar, or cerebral lesion. He had seen in consultation cases in which the diagnosis of brain tumor or meningitis had been made. He would, therefore, emphasize that during the prevalence of poliomyelitis, patients presenting cerebral, bulbar, or cerebellobulbar symptoms should be closely scrutinized lest they have cases of poliomyelitis of unusual localization. Unless the physician was aware that in the aberrant types the disease might attack practically any part of the brain or cord he was likely to be misled in diagnosis. On the other hand, instead of the abortive case the physician might be confronted with febrile symptoms of the most severe character. In three such cases of which he had knowledge the condition had been thought to be cerebrospinal meningitis, tumor, or abscess; in two instances, typhoid fever of the cerebral type. Since the disease prevailed epidemically in June, July, August, and September, whenever possible, children of an infected community who presumably had not been infected, should be removed to places supposedly immune. It should also be remembered that children should not at once be mixed with others who had been brought from a region in which the disease had not existed. Emphasis was placed upon the necessity of isolating children removed from a locality in which the disease was epidemic until the period of incubation was past or after the elapse of two or three weeks.

Poliomyelitis; Diagnosis.—Dr. JAMES H. MCKEE remarked that there was little that was characteristic about the onset of poliomyelitis, many of the symptoms simulating those of other infections and of some autointoxications. There was nothing typical connected with sudden onset, with moderate fever lasting usually for several days; the constitutional symptoms, or the fact that the attacks sometimes followed other infectious disease. This was particularly true of the polioencephalitis types. The nervous symptomatology, however, was suggestive during the prevalence of epidemics. It was not usual for babies and very young children to have severe pains in legs, arms, fingers, and toes, and to have headache and backache. This was also true of the associated general tenderness, and the rigidity of the neck. There were relatively few things in early life that caused such symptoms. Laboratory examination of blood and of the spinal fluid here gave undisputed evidence. Another symptom uncommon in infancy and early childhood and which often led to the diagnosis of "rheumatism" was profuse sweating. Scurvy was to be considered in the differential diagnosis. This, however, was a chronic affection with slow onset and definite history, and usually afebrile. Tonsillitis in early life might be accompanied with severe pains. In the various conditions to be considered, however, the laboratory gave convincing aid. In the treatment of the paralysis the patient should be mainly under the care of the orthopedist.

In the prevention of poliomyelitis, prophylaxis in general was to be observed. Since the disease occurred particularly in the hot months of the year children should be taken out of the large cities. The patient should be segregated, much attention should be paid to the care of discharges of the nasopharynx and of the bowels; animals might be carriers and should be excluded from the patient. Attendants should wear uniforms, and preferably, rubber gloves. Cleansing of he nasopharynx was highly essential. The bowels should be opened freely; nothing better for this probably than calomel followed by oil or salines; or the giving of hot baths with as little disturbance of the patient as possible. Since sweating was probably one of Nature's efforts to eliminate toxins, this should be increased as much as might be proper. In the presence of meningitis, lumbar puncture seemed wise for the reduction of pressure and the lessening of toxicity. Great emphasis was laid upon the necessity of absolute rest and quiet. The protection of the paralyzed parts with cotton, wire frames, etc., was essential to successful treatment. Voluntary activity should be resumed very slowly. Hope for recovery of the paralyzed part should obtain, not only for a year, but for many years.

Poliomyelitis; History.—Dr. PAUL A. LEWIS recalled that six years previously, before the College of Physicians of Philadelphia he had given a summary of what up to that time had been done in the study of poliomyelitis, which summary had been given from the results in the laboratory of the work of Dr. Simon Flexner and himself. Two years ago, Doctor Flexner had made a statement of the work he had done with other associates in the meantime. Since then little progress, Doctor Lewis said, had been made. With Doctor Mills and Doctor McKee he could in no way disagree; they had covered the ground so far as their statements went. He referred to the article by Doctor Flexner appearing in the *Philadelphia Public Ledger* for the 9th inst., in which the author had summarized his experiences in the matter of poliomyelitis. While there were slight corrections to be made in the publication, so far as the laboratory work was concerned the latest evidence was given. Doctor Lewis in giving his own experiences, said that as all knew, poliomyelitis was understood to be an infectious disease and in greater or less degree contagious. Its cause was known, and to the elect few who had had opportunity to work with the disease in the laboratory its cause might be said to be well known. The essential cause had been discovered six years ago: three years ago, with the actual cultivation of the organism, by Flexner and Noguchi, the causative organism had become more perfectly known. Six years ago, inoculations had been made from the spinal cord of the human dead of the disease into the monkey's brain and the disease had been reproduced in characteristic fashion. From the infected monkey the disease had been transferred through others to many hundred, and up to the present time the series had possibly reached hundreds of actual passages. It had been found shortly after this that the infectious material from the central nervous system of the human subject could be passed through filters sufficiently small to remove the bacteria, and there would still be a fluid highly infectious. This, he said, established the fact that the microorganisms were of well known bacteriological status, small enough to be passed through filters, and difficult to see under the microscope. Some such might be bacterial in nature and could be cultivated as were other bacteria; others were probably protozoa, such as the virus of yellow fever, and transmissible only through an intermediate host. The virus of poliomyelitis seemed to be of the former class. While it had been said that the organism was ultramicroscopic, it could be seen. It was so small, however, that nothing could be told of its structure as was possible with, for example, the tubercle bacillus. While the cause of poliomyelitis had been made known chiefly through the work of Flexner and his associates, these experiments had been confirmed and extended by others. In regard to transmission, that study had revealed to a certainty that it was by contact. On the other hand, there might be other methods of transmission Certain bizarre facts in connection with the disease were not easily explained on the basis of contact. They could not go astray, however, in taking the assumption of contact as the starting point of combating an epidemic. One difficulty in guarding against contact was because many cases were abortive to the extent that the individual showed no sign necessitating the calling of the physician and no sign which would lead the physician to be positive in his opinion whether the patient had been suffering from any infection, to say nothing of poliomyelitis. The cases with absence of paralysis were quite as dangerous to the unaffected as the paralytic. He expressed the fullest assurance that the Department of Public Health was fully equipped to deal with an epidemic, should such an unfortunate occurrence take place in Philadelphia. In the study of the epidemiology of the disease, under certain conditions the laboratory could help greatly. The laboratory, however, had done its best work in showing that individuals in contact with the infected were frequently carriers of the disease. The laboratory had also confirmed the clinical observation of the existence of a mild abortive or subparalytic form of the disease. Furthermore, the presence of the virus in the nasal secretions had been demonstrated. Emphasis was placed upon the fact that the laboratory showed the importance of prophylaxis from the standpoint of the contagiousness of the disease. In the therapeutic control of the disease the laboratory had produced nothing of practical importance beyond the fact that certain experiments by Flexner and his coworkers had shown that the serum of immunized animals and some chemicals could under certain conditions mitigate the disease in monkeys. On the other hand, the fact that these workers had not shared their work with the public was to him sufficient evidence that they had not found a cure for poliomyelitis. Anything that the newspapers might say to the contrary should not cause excitement.

Infantile Paralysis; Prevention.—Dr. J. TORRANCE RUGH said that the treatment of the ravages of infantile paralysis devolved ultimately upon the orthopedic surgeon. There were, however, many things which the general practitioner should know

regarding the care of these patients during and following the attack. The great essential in the after-treatment of these cases was absolute rest. They would be importuned by the family to allow the patient to sit up, or to move the affected leg or arm. They must not let it be moved; they must keep that part still, at absolute rest! The treatment as advocated by Oppenheim and elaborated by Lange of fixation in plaster of Paris to secure rest, essential for restoration of function and the carrying away of the products of the inflammation, had given by far the best results in these cases. The great trouble, however, was the difficulty in securing the cooperation of the family in allowing such fixation. Any treatment, so far as their experience went, which was directed to the nerve centres themselves had met with utter failure. Certain electrotherapeutists alleged ability to restore to a very much greater degree the nerve function of these nerve centres than could be accomplished by any other means. But here entered the great problem to which Doctor Mills had already called attention, that in all grades of infection, from the abortive to the fulminating, no man living knew how far recovery of paralysis would take place without any aid whatsoever. Some of these cases which had been totally paralyzed, ended in recovery with apparently no evidence of the disease. Therefore, to ascribe to any one method of treatment curative effects so far as the nerve centres were concerned, was entirely out of the question. Their efforts must be directed chiefly to the care of the paralyzed parts. There was too great a tendency to begin the use of massage and electricity too early. These muscles must be put at complete rest until all evidence of the acute condition had subsided. Then the tonic treatment by massage, electricity, or whatever means were employed, should be begun in the endeavor to maintain the tone of the muscles and the life of the muscle fibres. The muscles were kept at rest to guard against any strain which tended to increase degeneration of the fibres. There must be also the prevention of faulty postures. As a result of the acute inflammation in the structures faulty postures began extremely early, even before they showed themselves to the eye or the finger of the examining surgeon. If the paralysis affected the trunk muscles, the child should not be allowed to sit up. If the paralysis affected the legs, the patient should not be allowed to walk, as there was nothing to maintain the weight of the body, except the ligaments, and they were insufficient unless supported by the muscles. Therefore, when the muscles were paralyzed, the earliest thing to do was to keep the parts absolutely at rest, keep them from assuming a deformed position, and guard them against strain. When the child began to walk, the extremities should be maintained in their proper position. It was surprising in many instances, the great amount of power which would return after four or five years when these muscles which had been subjected to constant strain, had been protected and the parts maintained in the proper position. If there was any tendency to deviation from the normal position, a brace should be applied to the part. The indications for the application of braces were definite, whatever condition might be present and no brace should be applied, except to accomplish certain absolute needs. The therapeutics of a brace were as accurate as those of a drug.

Another measure of value to be employed early was that of having the patient practise voluntary movement of those muscles which had not been totally paralyzed. By giving the child voluntary control over a group of weakened muscles, the opposing muscles would be prevented from drawing the part into a deformed position, and when the child walked he would be able to maintain a correct position. In cases in which there was total loss of power, operation offered a great deal in treatment. This, however, brought in a portion of the work which belonged to the specialist, and any man who attempted work of this kind unless he was trained to it, would meet with absolute defeat in the treatment of these cases. The surgical treatment of infantile paralysis was divided into the two great classes of destructive and constructive surgery. Constructive surgery was indicated after two years had elapsed since the attack of the paralysis, and consisted chiefly in the transposition of tendons, silk inserts, and similar measures. Destructive surgery, which aimed at securing stability at the expense of certain structures of functions, should not be employed until six years had passed, and in the selection of operations, those which utilized structures already existing were to be preferred to those which made use of foreign substances for various purposes.

Dr. Wilmer Krusen, director of Public Health and Charities, Philadelphia, said that of the two cases of reported infantile paralysis now in the Municipal Hospital, one was a case of true infantile paralysis; the other, a case of infantile paralysis, but not of the poliomyelitic type. They had found that the child's paralysis was due to a cerebral abscess following middle ear disease. They had, therefore, only one case of true infantile paralysis. They could readily understand that with such a severe epidemic in New York and Brooklyn, their work in connection with the department of health had been most aggressive. While they believed in preparation for a possible epidemic, they did not believe it wise to frighten either the public or the profession. They had wards available in the Municipal Hospital to take care of at least 100 cases. If necessary it would be possible to have other general hospitals set aside certain space. He wanted to take this opportunity to thank the pediatrists, neurologists, orthopedists, and all others who had given their time and service in the last few weeks in assistance to the department of health. They had been trying to educate the family to send for the physician promptly when illness occurred among the children. They would pursue in poliomyelitis the same stringent measures observed in cases of smallpox.

Dr. John F. Sinclair, president, Philadelphia Pediatric Society, was glad that for the present the misfortune of an epidemic of infantile paralysis had not come to them. It seemed imperative, however, that they should be alive to the questions connected with this disease and be prepared to meet them if they must. Personally, he wanted to thank those who had been so ready to cooperate, the many who had

shown their interest in the subject by the large attendance at this meeting, the College of Physicians for giving them the use of the room, as well as the essayists of the evening.

Dr. D. Braden Kyle laid emphasis upon the responsibility of the upper respiratory tract for the infection and spoke upon prophylaxis and treatment from this standpoint.

Dr. Charles K. Mills was not yet aware of the manner in which poliomyelitis was transferred from one geographical locality to another; they saw it appearing in widely different sections with great intermediary regions free from the disease. In the migration of the contagion not enough attention had been paid to the part played by animals and to the birds of the air. The possibilities offered a fascinating subject for study.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, May 16, 17, and 18, 1916.

The President, Dr. W. Stanton Gleason, of Newburgh, in the Chair.

(*Continued from page 143.*)

The Pessary in Retroversion and Prolapse (*concluded*).—Dr. Robert L. Dickinson would give his patient written directions as to treatment, as in this way serious retroversion could be prevented. In the post partum group, examinations should be made at two weeks, six weeks, and three months post partum. If patients were well taken care of, then operation later could be avoided. The bad risks, the women with diabetes, tuberculosis, or sclerosed arteries, in whom resistance was poor, were poor subjects for operation. Those naturally fell into the pessary class and the pessary relieved constipation and improved general health.

To the operative class belonged the cystocele and rectocele group. He was more inclined than formerly to operate upon elderly women. They stood operation well and might have twenty years to live. They should have a choice of operation or be told that they would have to wear a pessary the rest of their lives. Working women as a rule should be operated upon. They had no time to call on the physician to be examined. In the case of young girls it was better to do an operation than to give them the office habit. There was distinct use for a pessary for a few months after operation until the organs had had time to recover tone.

With regard to the kind of pessary, there were many, and the one that the patient wore with comfort and could handle herself was the one most likely to suit that particular case. The patient should be instructed how to remove and cleanse it; scrupulous cleanliness was important, and she needed regular douching. If this was attended to, ulceration need never occur. The pessary could be taken out at night and put in again in the morning.

Dr. J. Riddle Goffe, of New York, said the usefulness and the definite limitations of the pessary in the treatment of retroversion and prolapse had been very clearly and convincingly presented by Doctor Dickinson. The pessary had a definite place in the treatment of those conditions, but it was only a temporary device, to be discarded and supplanted by operative procedure when the time and place served. Age was rarely a contraindication for surgical procedure in a woman who was able to be upon her feet. The operation of Doctor Vineberg's seemed to come into direct competition with supravaginal hysterectomy. There was no question about the superiority of the latter. In the completion of the operation the normal relation of parts was restored and the physiological function of the ligaments and the bladder maintained.

Dr. Thomas J. Watkins, of Chicago, said the pessary had a very important field, if a limited one. Its use could only be decided on by one who had done a good deal of work on the mechanics of the pelvis. As regards prolapse operations, he felt that Doctor Dickinson had mentioned a very important thing in regard to cystocele and rectocele, that was, conditions got worse, especially after the menopause, so that rectocele and cystocele must usually be corrected before they became extensive, so that operative procedures gave better results. In regard to the transposition operation, considering the results after eight or ten years, the more he studied the subject, the more and greater problems he encountered. There was no one operation that was best for prolapse of the uterus or of the bladder. Operative procedure should be modified to suit the case. Personally, he favored a modified transposition operation rather than hysterectomy.

Dr. H. S. Crossen, of St. Louis, was especially pleased to see the subject of the pessary so clearly demonstrated. He heartily seconded Doctor Watkins' suggestion that Doctor Dickinson should give the association a monograph on the result of his careful study of the pessary. The ball pessaries would slip out in half an hour. The Smith pessary and other forms would slip out. That class of cases was very troublesome; he had used the double horseshoe pessary. This should come into the hands of the general practitioner. It would be more and more used and understood. He had had a good deal of experience in dispensary work, and felt that no one could learn to use pessaries by descriptions, but only by personal practice. The horseshoe pessary could be left for a long time if the patient came at regular intervals for observation.

Dr. J. Wesley Bovee, of Washington, D. C., said in regard to the operative treatment, the further they got away from any one particular operation, or from any one form of treatment, the safer they were. Those addicted to one form of operation would have to use pessaries after operation, not as some noted surgeons had done, shortly afterward as precautionary measures, but months later as reputation savers. The best time to use a pessary was before operation. A large proportion of cases could then be helped. If the pessary was the right one it would not give symptoms. If it gave pain it was not the right one. He agreed that the soft pessary was to be condemned; the hard rubber pessary was the best in use at present. The Hodge modification of the Smith pessary was the best type.

Dr. Richard R. Smith, of Grand Rapids, Michi-

gan, approved most heartily what had been said in regard to the indications for the use of the pessary and of operation in cases of retroversion, especially in regard to cases which should be left without treatment in any form. In young girls and in young married women before childbearing, there was nearly always a neurotic element, and the less attention called to the pelvis the better. In older women operation alone should be used in certain complicated cases. It would be well to bear in mind one thing. In women during the childbearing age there should be no operation to interfere with that important function. The function of childbearing was of infinitely more importance to women than the alleviation of any discomfort. After that period was over, other operations could be considered. He had had the best results from Doctor Watkins's operation. It had quite revolutionized treatment.

Dr. Leroy Broun, of New York, said regarding Doctor Vineberg's paper the problem was presented how to deal with large uteri involving myomata, combined with procidentia; in other words, those that could not be interposed. There were two ways: First, taking a wedge up out of the uterus and bringing it down so that it would not protrude from the vagina; and Doctor Vineberg's method of taking the uterus up into the anteroposterior diameter and making it shorter instead of narrower. There was only one objection, and that was, by pressure of the structures and closing anteriorly the anterior wall there was a predisposition to push down the cervix, such as occurred in two or three cases mentioned by Doctor Vineberg. The cervix must be well imbedded so that there could be no fulcrum action. He could not recommend such an operation in complete procidentia, but he felt that the operation that would give the best results would be complete hysterectomy, sewing together the broad ligaments, and putting the bladder on top.

Dr. Samuel W. Bandler, of New York, said on the first sign of retroversion the Smith-Hodge pessary should be introduced. When involution took place there was no longer retroversion, but retroflexion. It would be found necessary to follow this procedure in at least half of the post partum cases, and patients would do very well. The pessary could be said to be of value as a diagnostic factor. The patient came to the physician complaining of pelvic pain, and retroversion was found on examination. If, at this time, there were no complications, such as shortened ligaments, the patient could be directed to wear a pessary. If this same patient came back later and said that all her symptoms had disappeared, the diagnosis was made. The doctor could then give the patient the choice of wearing a pessary for the next twenty-five years or of having an operation and dispensing with the pessary.

The Genital Reflexes and Their Role in the Production of Symptoms Arising in the Pelvis.—Dr. Richard R. Smith, of Grand Rapids, said the genitourinary reflexes might be divided into two groups, first, those belonging to the spinal and sympathetic system; second, those of the higher cerebral centres. The first group were automatic, simple, and unconscious and were designated as subcortical, and the latter were psychic. The first group of reflexes were able to maintain normal generative functions, for women with transverse lesions of the cord were able to menstruate and conceive and have normal labors.

Dealing with various sympathetic reflexes they got such reflexes as contraction of the anus and perineum which was protective in character, contraction and retraction of the uterine musculature, and the production of secretion from the Bartholinian glands. The psychic reflexes belonged to the higher development of the brain. Their stimuli were physiological, the psychological beginning when the impressions had reached the cortex. Perceptions varied with the quality of stimuli. Only exaggerated processes reached consciousness. The mental make-up and the sum total of experience determined mostly the manner of the reflex. The purpose of some reflexes was clear, such as contraction at the fear of some object, or the production of secretion of the Bartholinian glands, but some reflexes were more obscure, such as blushing under embarrassment, or violent movements of the intestines under fright, or cessation of menstruation after shock or grief. These were all conscious reflexes, but some were not under the control of the will directly. The mechanism of emptying a full bladder illustrated the employment of both psychic and subcortical impulses. The application to gynecology was that the mental make-up of the patient might produce irrational ideas and distortions in the presence of a perfectly normal pelvis. When only slight lesions were present the mental picture must be considered as the direct cause of the symptoms arising from the pelvis. The stress of patients living under emotional unbalance produced exhaustion and fatigue, even under conditions that seemed to be conducive to normal life.

Letters to the Editors

THE TREATMENT OF ANTERIOR POLIOMYELITIS.

Brooklyn, N. Y., *July 23, 1916.*

To the Editors:

A great deal is written, both in our medical journals and the lay press, about poliomyelitis, its causation, symptomatology, progress, and methods of prevention—which is all very good, but little is said about its medicinal treatment. It is practically ignored. Therapeutic nihilism is progressing disgracefully the world over. If the members of the medical profession would thumb their materia medica and master the therapeutic effects of drugs as assiduously as they study pathology, the internal secretions, surgery, the vaccines and antitoxins, I do not believe that this sudden epidemic of poliomyelitis would have reached such widespread proportions and caused such consternation among medical men.

The cause, mode of infection, contagion, pathology, etc., are fairly well recognized. Let us get down to medicinal treatment.

Veratrum viride, a vasomotor depressant, lessens the vasoconstriction and hyperemia of the cerebrospinal system; it is especially indicated in poliomyelitis when there exists a hyperemia of the cord and meninges.

Aconite, by dilating the peripheral arterioles, improves the tonicity of the mucous membrane of the nasopharynx and undoubtedly inhibits the activity of germ life at the point of invasion. I believe that if these two drugs are

used from the very beginning, the progress of the disease process is arrested. You obtain more abortive cases, fewer succumb, lessening the death rate; convalescence is shorter and the repair of damaged muscles is immediate and progressive.

Being called to a child with sudden fever, with or without vomiting or convulsions, with enlarged tonsils, and irritation of the nasopharynx, without other symptoms, clean out the alimentary tract, enjoin absolute rest and quiet, and prescribe veratrum viride and aconite, and watch developments.

My prescription is:

℞ Veratri viridis (Norwood's), ... ♏viii;
Tincturæ aconiti radicis, ... ♏l;
Syrupi simplicis, ... ʒss;
Aquæ, q. s. ad..... ʒii.

M. Sig. One teaspoonful every hour for twenty-four hours, and then the same dose every two hours.

After the acute stage has passed, the physical agents are used, viz., radiant heat and light, electricity, static or high frequency, until cured.

LIONEL C. CHARBONNEAU, M. D.

COCAINE CATARRH "CURES."

NEW YORK, *July 13, 1916.*

To the Editors:

The enclosed clipping is from the NEW YORK MEDICAL JOURNAL. Perhaps a little information regarding this subject might be of interest.

In the *Medical Review of Reviews* for June the charge is made that a physician was responsible for all the damage done by the four per cent. cocaine snuff once known as Doctor Cole's Catarrh Cure—Doctor Cole presumably being the depraved physician in question. There never was a Doctor Cole; the originator and owner of this preparation, as a matter of fact, was neither a physician nor a druggist; he was a manufacturer of several patent medicines and invented Doctor Cole, simply to secure what he considered a desirable alliteration. Thus one slur on the profession is disproved.

Somewhat over twenty-five years ago, there was a doctor in Omaha, Nebraska, by the name of B——, a nose and throat specialist of the quack order. He prepared a powder composed of boric acid, some inert vehicle, and cocaine—a four per cent. cocaine powder. This powder was sold direct to his patients and also through the retail drug stores, and if I am not very much mistaken, I was one of the first, if not the first, to detect the danger and habit forming qualities of cocaine, for within a very short time after this powder went on the market we had hundreds of people in Omaha who became addicted to its use, and for a number of years it was a hard struggle to eradicate the evils that this powder had started. If my memory is correct, this Doctor B—— had some trouble with a girl. Her father got after him and shot him, but the bullet struck his watch in the watch pocket of his trousers and he was only slightly injured. He left town almost immediately afterward.

EDWARD WALLACE LEE, M. D.

Book Reviews

Infections of the Hands. A Guide to the Surgical Treatment of Acute and Chronic Suppurative Processes in the Fingers, Hand, and Forearm. By ALLEN B. KANAVEL, M. D., Assistant Professor of Surgery, Northwestern University Medical School, Attending Surgeon, Wesley and Cook County Hospitals, Chicago. Third Edition, Thoroughly Revised. Illustrated with 161 engravings. Philadelphia and New York: Lea & Febiger, 1916. Pp. 498. (Price, $3.75.)

This is the third edition of Kanavel's work, which speaks well for its popularity and usefulness. The present edition has been thoroughly revised and brought up to date, while two chapters have been added, the first dealing with the Relation of Acute Infective Processes to Industrial Pursuits, while the second discusses Plastic Procedures Instituted for the Correction of Deformities. Dr. Henry E. Mock, who by reason of his connection with a large industrial concern possesses special knowledge of the subject, especially from the practical standpoint, collaborated with Doctor Kanavel in the preparation and compilation of the former chapter.

In Chapter XXIX the author has added a section detailing the results of his clinical experience in attempting to restore function to old contracted hands. After several of the chapters, résumés have been inserted which, it is believed, will aid the surgeon who is in haste for concrete knowledge concerning the contents of the work, but the author wishes to warn the student and surgeon that a comprehensive reading of the preliminary anatomical and experimental matter will be necessary for an accurate knowledge of the diagnosis of the various types of infection and the position of the pus in each type. In the first instance, it may be said that the book is excellently arranged and written in good concise English, a merit of no small value in a medical or surgical work. Perhaps the most important chapters are those on diagnosis and general principles of treatment, for when a reader in search of information is in doubt, he may turn to these chapters which indicate the group into which his case falls, and also direct him to the section of the book in which cases of that nature are treated more in detail.

Chapter XXV, already referred to, is of practical value, and from the points of view of prevention and treatment contains a fund of information which cannot fail to be useful to surgeons whose work lies in the care and treatment of the employees of industrial concerns. The entire question of hand and forearm infections is considered exhaustively, and the allied affections, such as erysipelas, erysipeloid, gas bacillus infection, and anthrax are discussed at length. The book concludes with a consideration of the complcations and sequelæ of infection of the hand.

Drawings made by Mr. Tom Jones replace the plates in the former editions, showing the dissections made from cross sections. The work provides a mine of information for the surgeon, which if he follows closely and skillfully and puts into practice the knowledge gained therein will undoubtedly result in the prevention and successful treatment of infections of the hand and forearm. The author particularly emphasizes the necessity for careful study of the diagnosis of tendon sheath infection, which, as he points out, is frequently overlooked until it is too late for satisfactory treatment.

Interclinical Notes

The *Survey* for July 15th discusses the local outbreak of anterior poliomyelitis as the Scourging of New York. It states that the disease was first described by an Englishman about the middle of the nineteenth century. Since 1905 the United States has distanced all other countries in the frequency of epidemics. It is interesting to learn that negroes are infrequently attacked, which seems greatly to complicate the question of etiology. The death rate of this epidemic is said to be twenty-one per cent., compared with only five per cent. in 1907.

* * *

A correspondent with the militia at the Mexican border writes to the *Sun* for July 23d of the great dissatisfaction among the enlisted men because there is apparently to be no fighting. The writer is careful to state that health conditions are excellent, and that only 1.5 per cent. of the men are on the hospital lists. The health conditions will remain good, he says, as long as the men are on the border; "the admirable medical corps of the United States army will see to that."

* * *

There are few writers for periodical literature who might not with advantage read the excellent summary in *Current Opinion* for July, of a chapter in Sir Arthur Quiller-Couch's recent book, *On the Art of Writing.* The chapter is on jargon, which Sir Arthur says has two chief characteristics. It uses circumlocution and it habitually chooses vague woolly abstract nouns rather than concrete ones. Jargon is evidently much used in papers and discussions at medical society meetings.

* * *

According to *Our Dumb Animals* for July, 1916, the director of the Zoological Gardens was on his holiday. He received a note from his chief assistant, which closed thus: "The chimpanzee seems to be pining for a companion. What shall we do until you return?"

Official News

United States Navy Intelligence:

Official list of changes in the stations and duties of officers serving in the Medical Corps of the United States Navy for the week ending July 22, 1916:

ARBUCKLE, L. D., Assistant Surgeon, Medical Reserve Corps. Ordered to duty at the naval recruiting station, Boston, Mass.

BIELLO, J. A., Passed Assistant Surgeon. Ordered to temporary duty at the naval recruiting station, New York, N. Y.

BOONE, J. T., Assistant Surgeon. Detached from the Marine Brigade, Haiti, and ordered to the Naval Hospital, Norfolk, Va., for treatment.

FAULKNER, G. E., Assistant Surgeon, Medical Reserve Corps. Ordered to duty at the naval recruiting station, New Orleans, La.

FOOTE, O. C., Assistant Surgeon. Detached from the *Tallahassee* and ordered to the *Delaware*.

GLENN, C. F., Assistant Surgeon, Medical Reserve Corps. Ordered to duty at the naval recruiting station, Burlington, Vt.

GREENOUGH, R. H., Assistant Surgeon. Commissioned an assistant surgeon, May 25, 1916.

JOHNSON, M. K., Surgeon. Detached from the *Montana* and ordered to the *Oklahoma*.

LANGHORNE, C. D., Surgeon. Detached from the *Oklahoma* and granted two months' leave of absence.

LYNCH, C. P., Passed Assistant Surgeon. Commissioned a passed assistant surgeon from February 19, 1916.

MCDONALD, HENRY, Assistant Surgeon. Detached from the *Colorado* and ordered to the *Pittsburgh*.

PRIEST, HOWARD, Assistant Surgeon. Detached from the *Delaware* and ordered to the *Tallahassee*.

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending July 19, 1916:

BANKS, CHARLES E., Senior Surgeon. Ordered to proceed to New York, N. Y., for duty in the prevention of the interstate spread of poliomyelitis.

BROWN, B. W., Surgeon. Ordered to proceed to New York, N. Y., for duty in the prevention of the interstate spread of poliomyelitis.

FOX, CARROLL, Surgeon. Ordered to proceed to Birmingham, Ala., for the study of public health organization and administration; granted leave of absence for one month and fifteen days from July 5, 1916.

FREEMAN, A. W., Epidemiologist. Ordered to proceed to New York, N. Y., for duty in connection with studies of poliomyelitis.

GARDNER, C. H., Surgeon. Ordered to proceed to New York, N. Y., for duty in the prevention of the interstate spread of poliomyelitis.

GUITERAS, G. M., Surgeon. Granted two days' leave of absence from July 13, 1916, under paragraph 193, Service Regulations.

HARRINGTON, F. E., Assistant Epidemiologist. Ordered to proceed to Birmingham, Ala., for special temporary duty.

HUGHES, T. E., Assistant Surgeon. Relieved from duty on the Coast Guard cutter *Seminole* and ordered to proceed to New York, N. Y., for duty in the prevention of the interstate spread of poliomyelitis.

MAGRUDER, G. M., Surgeon. Ordered to attend a conference on poliomyelitis at Portland, Ore., July 15, 1916.

MARSHALL, E. R., Passed Assistant Surgeon. Ordered to proceed to Boston, Mass., when convenient, for the observation of methods of examining arriving aliens.

MAYER, O. J., Acting Assistant Surgeon. Ordered to proceed to Galveston, Tex., for temporary duty, pending return to Tampico, Mexico.

MICHEL, CARL, Assistant Surgeon. Granted thirteen days' leave of absence from August 15, 1916.

MULLAN, E. H., Passed Assistant Surgeon. Granted fourteen days' leave of absence from July 16, 1916.

PARCHER, GEORGE, Passed Assistant Surgeon. Granted twenty-one days' leave of absence from July 17, 1916.

SCHERESCHEWSKY, J. W., Surgeon. Ordered to proceed to Youngstown, Ohio, to arrange for the continuance of studies of the health of steel workers.

SLAUGHTER, W. H., Assistant Surgeon. Ordered to proceed to Atlanta, Ga., for conference regarding studies of rural sanitation.

STEWART, G. McG., Acting Assistant Surgeon. Ordered to proceed to New Orleans, La., for temporary duty.

WILLIAMS, L. L., Jr., Assistant Surgeon. Relieved from duty on the Coast Guard cutter *Onondaga* and ordered to proceed to New York, N. Y., for duty in the prevention of the interstate spread of poliomyelitis.

YOUNG, GEORGE B., Surgeon. Granted twenty-one days' leave of absence from July 20, 1916.

Casualty.

Surgeon Charles Poindexter Wertenbaker died at Charlottesville, Va., the place of his birth, July 12, 1916. He was appointed an assistant surgeon in the Public Health Service, August 18, 1888, and was promoted to be passed assistant surgeon, September 2, 1892, and to be surgeon, February 16, 1904. Surgeon Wertenbaker served at various marine hospitals and quarantine stations of the Service, and was detailed for duty during the yellow fever epidemic in 1905. He was placed on waiting orders on account of physical disability, January 1, 1916.

Births, Marriages, and Deaths

Born.

DALTON.—In Burlington, Vt., on Thursday, July 13th, to Dr. Charles Dalton and Mrs. Dalton, a son.

GOLDSTEIN.—In New York, N. Y., on Thursday, July 13th, to Dr. A. Otto Goldstein and Mrs. Goldstein, a son.

NORTON.—In Fitchburg, Mass., on Saturday, July 15th, to Dr. George Paul Norton and Mrs. Norton, a daughter.

Married.

HESTON-MURPHY.—In Tacoma, Wash., on Monday, July 10th, Dr. Edward Calder Heston, of Roslyn, and Miss Mary Murphy.

MCHUGH-MCKENNA.—In Hartford, Conn., on Tuesday, July 11th, Dr. Arthur M. McHugh and Miss Alice Mary McKenna.

STREETT-WESTCOTT.—In Baltimore, Md., on Wednesday, July 19th, Dr. David Corbin Streett and Miss Ferebe Guion Westcott.

YOUNG-BELLIS.—In New York, on Saturday, July 15th, Dr. John H. Young, of Montclair, N. J., and Miss Gertrude Bellis, of Washington, D. C.

Died.

BARNHART.—In Huntington, N. Y., on Thursday, July 13th, Dr. Isaiah Charles Barnhart, of Brooklyn, aged sixty-eight years.

BAXTER.—In Cleveland, Ohio, on Sunday, July 9th, Dr. Harris H. Baxter, aged sixty-nine years.

CASSELBERRY.—In Lake Forest, Ill., on Tuesday, July 11th, Dr. William Evans Casselbury, of Chicago, aged fifty-eight years.

COTTON.—In Chicago, on Wednesday, July 12th, Dr. Arthur Cleveland Cotton, aged sixty-nine years.

DRAKE.—In Norwich, N. Y., on Wednesday, July 12th, Dr. James B. Drake, aged sixty-three years.

ELMENDORF.—In Port Chester, N. Y., on Tuesday, July 18th, Dr. Thomas C. Elmendorf, aged sixty-three years.

FLYNN.—In Jeffersonville, Ind., on Sunday, July 9th, Dr. Edward N. Flynn, aged forty-eight years.

HASKELL.—In St. Louis, Mo., on Thursday, July 13th, Dr. William A. Haskell, aged seventy-two years.

HODGES.—In Cavendish, Vt., on Tuesday, July 11th, Dr. Edward Francis Hodges, of Indianapolis, Ind.

HUGHES.—In St. Louis, Mo., on Thursday, July 13th, Dr. Charles Hamilton Hughes, aged seventy-seven years.

MARSHALL.—In Cowan, Ind., on Monday, July 10th, Dr. Reuben Marshall, aged seventy-six years.

OVERBECK.—In Rockville, Ind., on Monday, July 10th, Dr. Charles W. Overbeck, aged thirty-seven years.

PUTNAM.—In Jersey City, N. J., on Thursday, July 13th, Dr. Charles E. Putnam, aged sixty-one years.

SHILL.—In Lafayette, Ind., on Saturday, July 8th, Dr. Charles W. Shill, aged sixty-five years.

WERTENBAKER.—In Charlottesville, Va., on Wednesday, July 12th, Dr. Charles Poindexter Wertenbaker, surgeon, United States Public Health Service, retired, aged fifty-six years.

SHOES, PHYSIOLOGICAL AND THERAPEUTIC.*

BY DEXTER D. ASHLEY, M. D.,
New York.

No one should try to combine all qualities in a single shoe to meet all conditions, occupations, and positions in life. The more quickly we find that there are vast differences in the requirements of the feet in various occupations and environments, the sooner shall we be able to avoid the ruts in dealing with the shoe problem. In practice we must consider the status of the patient. A lady who stands and walks little may wear almost any shoe with comparative comfort. The pinch comes when some shop girl who stands on her feet all day tries to wear the same style of shoe.

The lay conception of the normal foot's form, function, and natural movements is so hazy, and the mind is so saturated with the ideas of fashion in footwear, as to require the patience of a Job, the suavity of a Chesterfield, and the diplomacy of a Bismarck combined to deliver a really comfortable, physiological shoe.

Children, adolescents, and adults who are suffering severely will accept somewhat radical changes in footwear, and with these we may hope to approximate our ideals. The man who has any extensive practice in treating foot conditions, will have full opportunity to use all his medical and surgical skill. Some cases will prove most baffling from a pathological or psychological standpoint. In prescribing shoes, the doctor's path will be smoother if he can modify the shoes commonly worn by the patient, or if these are impossible, direct him to select a fairly good trade shoe to be modified. Seldom is the custom shoe perfect or exactly as designed, and the patient will expect much more from the "made to order" shoe in the way of immediate relief of symptoms, correction of deformity, and indefinite wearing qualities.

Happily the trade has provided children's shoes which somewhat approach the physiological outline of the foot. The trade offerings of shoes for men which approach the physiological outline are increasing in number. Women's and misses' shoes which conform to these lines are scarce articles. Of these some are hobby ridden, or are too rigid in design to meet the requirements of the large majority, and so repel many who are looking for a physiological foot covering. On the other hand, to the general mind an orthopedic shoe is a fright—clumsy, heavy, stiff, and deformed—an object to be avoided, owing to the fact that not a few shoes masquerading under this name entirely answer the description.

In the following paper the writer finds it convenient to consider, first, the common shoe for every day working and walking. This shoe should be a physiological one for approximately normal, strong feet. A conception will be offered of what this should be, with citations of the most common faults to be found in the trade offerings of the ordinary shoe. The dress shoe is not especially considered. It is self evident that these shoes should be light and neat, and should conform to the physiological requirements and anatomical outline of the foot, without constriction. The consideration of shoes to meet the needs of various occupations, vocations, and climatic conditions, will not be entered into. The therapeutic shoe, prescribed to meet the various symptoms of mechanical strain, weakness, or disease, to prevent deformity or correct such conditions as may be controlled or influenced, will be discussed. Under this head will be considered the prescription or custom made shoe with individual lasts, the plaster of Paris last, and some of the difficulties met by the practitioner in obtaining a shoe as prescribed. Modifications of the common shoe and the commercial therapeutic shoe will be taken up, and an examination made of the commercial offerings of therapeutic shoes designed to meet the demands of the trade.

Comparing the outline of the foot with the shoe of civilized man, ordinary shoes would appear as a monstrosity to us were it not that long association with these forms has dulled our perceptions. To make more apparent the difference between the ordinary shoe and the normal foot, the former, conventionalized, may be indicated by the outline of the isosceles triangle upon a rectangle (Fig. 11), the toe of the shoe corresponding to the most acute angle. The conventionalized outline of the normal foot would be that of a truncated obtuse angle triangle, the toes occupying the broad part of the triangle, the inner side of the foot corresponding to its long side (Fig. 12).

The physiological shoe for approximately normal, strong feet should conform to the foot outline when in action, without undue restraint. The sole should

*See Dexter D. Ashley, this JOURNAL for February 19, 1916.

be strong, elastic, straight to the floor line, with sufficient curve to prevent stubbing. It should be broad enough to carry the vamp, and may have a pointed or rounded tip. The centre of the sole should correspond with the centre of the foot. The welt should be wide enough to protect the vamp (see Fig. 13, illustrating various parts of the shoe).

The insole should be of flexible leather, "good grade shoulder," well hammered or rolled, and should be flat or very slightly convex in the anterior part behind the anterior metatarsal arch.

The shank should be rather narrow, yielding, and elastic, tending to the outer side, giving a neat internal arch.

The heel should be as wide as the individual's heel in a snug counter, and five eighths to one inch high for adults. It should be built straight down from the rand or lower edge of the counter on the sides, and be set well forward, centring under the

A B

Fig. 11.—Radiographs of left foot without shoe and right foot within the shoe of the same individual. A, Note the exceeding width of the nonconstricted foot; B, note that this shoe shadow fills the isosceles triangle upon a rectangle, the conventionalized shoe.

os calcis, with "full pitch" behind. Individuals compelled to stand or walk for long hours upon unyielding surfaces would do well to have a rubber or cork heel, or rubber or cork covered by a lift of leather. The breast of the heel should be as high as or higher than the posterior elevation by one to one and a half lift.

The counter should be comparatively snug, low, and strong, grasping and conforming to the heel of the individual. The counter and upper should follow the contour of the heel behind, facilitating the placing of the heel of the shoe well forward under the calcaneus.

The heel cavity, or seat, should be slightly concave and yielding, conforming to the wearer's heel.

The vamp should be straight on the inner side to the end of the great toe, and then begin to curve or to point inward toward the centre of the shoe, to form the tip. The outer border, conforming to the foot, should increase in width forward to the end of the little toe, and then curve inward to meet the great toe curve or point. It should be broad and full across the ball, permitting free motion in the anterior part of the foot. The internal arch should be neat, with no more pressure than would be encountered in walking barefoot over slightly yielding earth.

The instep should be neat over the internal arch, and should not constrict the foot over or anterior to the tarsometatarsal joints.

Lacings in shoes afford better, more accurate adjustments to the inequalities of the foot than buttons. They should not be tight anterior to the proximal ends of the metatarsals, as this would impair the movements of the anterior foot. The tarsometatarsal joints, coming under the lacings, are frequently the seat of exostoses and rheumatoid deposits, due largely to irritation produced by constriction of the circulation at that point, or pressure of foot plates below, or both. The annular ligaments (ligamentum transversum cruris and ligamentum cruciatum cruris) suggest by their function the natural and convenient point where a close lacing may best be tolerated, which will prevent slipping up and down of the heel, or motion forward and backward in the shoe. This slipping can be controlled by using the rough side of the leather on the inside and providing a secure heel seat.

Fig. 12.—A radiograph of the foot of a ten year old child within the truncated obtuse angle triangle—the conventionalized foot.

High shoes have their principal use as a protective covering. They restrain the natural function

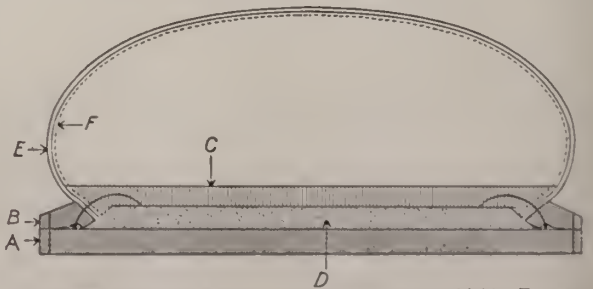

Fig. 13.—A, sole; B, welt; C, insole; D, fill (too thick); E, vamp; F, drill lining.

of the ankle in all directions, and consequently are an inhibiting factor to all strong muscular activity.

It is evident that such physiological shoes as described above would not meet with general approval today, nor would they be comfortable at first to the majority, since most feet have become accustomed to unnatural positions and support, and to place them at once in an approximately physiological position, would arouse at first many pains and joint grumblings. A new set of muscles, ligaments, and weight bearing facets is called into use. The unshod individual is a plantigrade. Most of our shoes make him nearly related to the digitigrade, the foot functioning in the position of talipes equinus, carrying the weight upon the less stable anterior part of the foot.

Without exception, the ordinary shoe is too narrow across the ball of the foot, preventing free motion of the toes. Often a wide shoe has no more leather in the vamp than a narrow one, hence the toes are pressed upon, and corns are produced, as the foot is driven forward into the anterior part of the shoe by the body thrust at every step, this thrust being enhanced and directed by the elevated heel and unstable heel seat.

The inner vamp line invariably starts to curve inward toward the centre of the shoe at the ball of

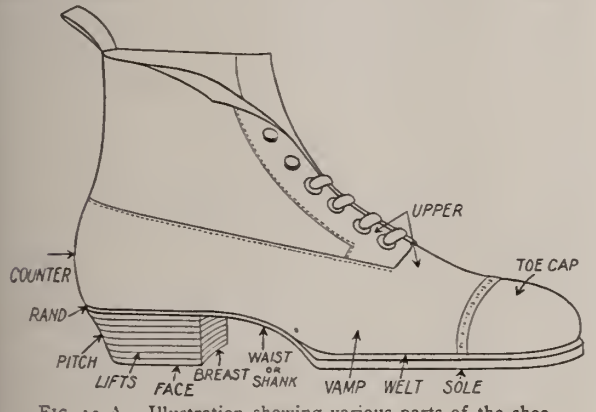

FIG. 13 A.—Illustration showing various parts of the shoe.

the foot, pushing the great toe inward to the centre of the foot, producing deformity—hallux valgus. The natural straightforward position of the great toe, as pointed out by Meyer[1] is destroyed, and the efficiency of the foot as a machine is very materially reduced.

The counter is quite out of proportion to the size of the heel of the wearer, being too broad and permitting the heel to move from side to side.

The heel seat is wide, flat, and of adamantine hardness, frequently rough, making a square edge at union of counter and heel. In the standing position the cushion of the heel is crushed at the point of contact with the hard heel seat and escapes at either side and behind into the square space at union of heel and counter, forming callosities on the edge and side of the heel (Fig. 14). The tubercles are sometimes almost denuded of their natural cushion by the pressure atrophy caused by the unnatural weight upon the small bearing surface. This is the source of many painful foot conditions, the discomfort being attributed to the falling longitudinal arch.

[1]Herman Meyer, *Why the Shoe Pinches.*

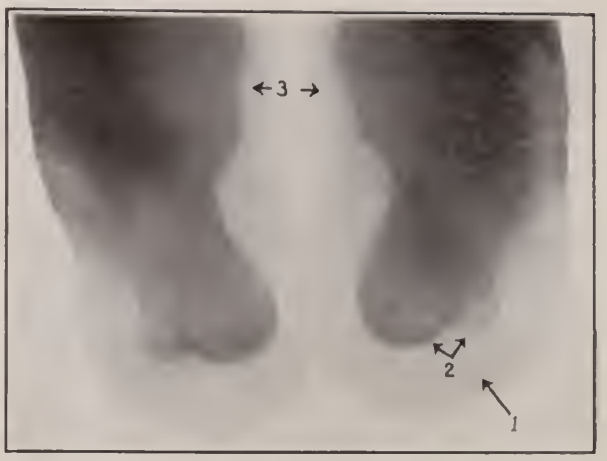

FIG. 14.—Radiograph of heels from behind. 1. Fatty (fibroconnective tissue) cushion. 2. Great and lesser tubercles seen in relief. 3. Suhastragaloid joint and sustentaculum tali. This part of the foot, the heel, may be fitted snugly without impairment of function. The measure for this snug fitting counter should be taken with outside callipers. The plaster of Paris cast will not give this measurement since most heels have been flattened by the flat heel seat. The heel can generally be compressed one quarter to one half inch. If the heel seat fits the heel of the wearer there will be no slipping from side to side and the motion from behind forward wedging the toes will be reduced to the minimum.

The dead tired feeling experienced by those who stand much upon hard floors when wearing comparatively low, inelastic heels, may be referred to this faulty heel seat. All painful heels—the "policeman's" heel, the spur heel, the hemorrhagic papilloma of the heel—are either caused or influenced by this unyielding heel seat and the fact that the counter does not conform to the counter of the wearer's heel. We are likely to see more of these cases, as the comparatively low heel and wide counter of the prevailing style in men's shoes must aggravate atrophy and thinned cushions, since the lower the heel, the more weight to be carried in the heel seat. This fault has been recognized by the trade. A shoe was discovered some weeks ago, which had been designed to conform to the heel to relieve these conditions.

The heel is almost always too high and narrow, especially in women's shoes. The high heel and broad counter, or even moderately high heel—one and one half inch high—precludes the possibility of wearing a broad toe (the physiological toe with straight vamp line to end of the great toe) with sat-

FIG. 15 A.—The "wedge heel" in a custom made shoe—counter and heel seat do not conform to the contour of the heel. The foot rests upon an inclined plane—the foot must slip forward and leave a cavity behind the heel.

isfaction or even with comfort. A broad toe, with the ordinary heel seat, permits the foot to slide forward. Soon the shoe is discovered to be apparently too short, with a disagreeable sensation in the great toe, and the two outer toes become cramped upon the outer curve of the shoe.

When the anterior elevation of the breast of the heel is one fourth to one half inch less than the posterior elevation, we have a "wedge heel" (Fig. 15, A, B, C, D). It is easily appreciated that such a heel, which is very common in the ordinary shoe for men and women, would faciliate the slipping forward of the foot. The only possible advantage of the "wedge heel" is to exaggerate the height of the wearer. The heel seat becomes an inclined plane, an unstable rest, upon which the heel in the ordinary shoe slips forward at each step, thrusting the anterior foot into the "wedged toe" of the shoe. It is evident that in such a shoe the heel may be comparatively low, and the entire shoe large and loose, and yet be the fruitful cause of painful corns, bunions, hallux valgus, flexed toe, hammer toe, and callosities. Many men and women who have worn

Fig. 15 B.—Ordinary shoe—one and three-fourths inch heel—marked inclined plane. Dotted lie indicates a better position for the heel which would have shortened the long shank. Just a little worse than A.

comparatively sensible, roomy shoes with low heels have these affections well marked. This same mechanical condition is produced when the heel seat is covered by a wedge of cork or rubber, or when the arch of the moderately high heeled, cheap shoe breaks down. This is the shoe which Doctor Gibney has warned us not to wear.

In a few shoes the breast of the heel is higher than the posterior elevation (Fig. 16). This heel, when not more than one to one and one half inch high, lifts higher in front, and when combined with a snug counter and depressed or yielding heel seat, adds greatly to the stability of the heel seat and prevents the heel from slipping forward—a combination that the writer has never met in the trade shoe.

The greater elevation of the breast may be found in some shoes approaching the physiological, especially those with the flexible shank, though their heel seat is hard and the counter too broad. Apparently the manufacturer has endeavored to support the arch of his flexible shank by the elevation of the breast. So long as the heel is below one inch, it seems to be quite efficient.

In men's shoes the heel is often too high and long, increasing the leverage of the arch by extending backward (Fig. 17). The heels of ordinary shoes al-

Fig. 15 C.—Wedge heel, by wearing off the anterior part of face and breast of the heel becomes a drag-heel. The long shank bridged by a foot plate has given way. The iron clip nailed to the outer and back side of the face to prevent its wearing away, and the long shank have helped to make this a bad heel.

ways, and of stock orthopedic shoes almost always are built higher on the outer edge and side (Fig. 18), tending to destroy the balance of the foot and lower the longitudinal arch. The long, narrow heel gives no stability or correction of balance. There are not a few heels very much too wide, and these, evidently intended to facilitate balance, are quite as high or higher on the outer edge, destroying the balance. This applies especially to trade therapeutic shoes, which will be described later. Again, the heel is apt to be built straight down from the rand, slightly flanged, or extended outward and forward on the outer edge, and given a pitch outward, cut away on the inner edge, removing support at this point, all tending to destroy balance and make the foot assume a position of pronation, thrusting the weight and strain on the weaker structures of the inner side of the foot. Without exception shoes that are considered sensible have heels that are unduly lengthened behind, being one half to three fourths inch longer than they should be, considerably increasing the weight of the shoe and the leverage on the longitudinal arches. This is to be seen especially in men's shoes (Fig. 17). When the heel is built straight down from the counter, as frequently happens, we have the "drag heel." The cheap shoe with high heel and broken shank gives another illustration of the "drag heel" effect upon the arch (Fig. 17, A, B, C). The well worn shoe of the derelict illustrates the worse effect of the "drag heel."

Skiagraphs of the foot (Figs. 15 and 17), taken

Fig. 15. D.—Cheap shoe broken down by excessive weight. Heel tips up behind under weight, breast and anterior face having been worn away—the drag heel of the derelict. This gives a good example of the position of the foot, and the added leverage upon the arch by the neglected heel.

through the shoe, well illustrate this mechanical disadvantage and faulty construction. Note the undue prolongation of the heel of the shoe and the cavity behind the heel of the wearer. When the heel is lowered to a height of one inch and built straight down from the rand, this mechanical disadvantage becomes very evident, especially if the shoe combines an elastic or flexible shank. This is an unnecessary

Fig. 16.—This shoe built by trade on an especially prepared last for this foot. This is an example of the heel with the breast higher than the posterior elevation. Heel fits quite securely in heel seat and counter. A "full pitch" to the heel behind would have relieved weight and made a neater appearance. Pen line indicates depression of depth of heel seat. Nails are on the sides, not in the heel. The shoe was found to be out of balance, owing to the sole having been cut away too much in the region of the ball of the great toe. The foot had a distinct tendency to pronate. This illustrates the difficulty of obtaining a shoe as required after furnishing the last.

disadvantage of the low heeled shoe. The rand may be shifted well forward if the counter follows the contour of the wearer's heel. This would permit the first heel lift to be three eighths to one half inch farther forward, even in low heels. The heel should be built with "full pitch" behind, when the posterior heel is brought forward under the calcaneus, approaching the support of the Cuban or Spanish heel. The more we lower the heel, the more care should be given to the position of the heel line, both for appearance and for prevention of unnecessary leverage upon the arch.

One of the greatest problems that the orthopedist

Fig. 17 A.—The long "drag-heel"—this heel is too long, wide, high, flat and hard. This style of heel is peculiar to numerous makes of trade shoes. Noting the position of this individual's heel in this shoe, it will not require much discernment to realize that this foot is working at a great disadvantage. The exceeding width of the heel counter cannot be depicted in the x ray. Heel seat is very insecure and toes are wedged.

meets in treating weak feet is to provide a heel that will not offend the sensibility, the preconceived sense of elegance, beauty, fashion, or fancy. With many patients the excuses for high heels are very

Fig. 17 B. "Drag heel" in the low heel custom made shoe. Heel seat is hard and flat, slightly relieved by rubber heel—square corner at edge of counter and heel. Wearer complains of dead tired feeling. Heel cushion is flattened by weight in low flat heel seat. Examine the lasts upon which these shoes are made and it will be seen how impossible it would be to make the counter and heel seat conform to heel. The lasts are *flat in the heel and square at union of counter and heel.*

apparent. The writer must admit sympathy with exceedingly short individuals, be they men or women. The tall young lady, too, is often an acute sufferer from the high heel and pointed toe which mask while they distort, warping and crushing the foot into a semblance characterized by society as a civilized pedal extremity. It is contended that the heel elevates the wearer out of the mud and slush of the streets. To attain this end, the sole should be elevated also. On the contrary, the excessively high heel is generally accompanied by a very thin sole. The soles of women's walking shoes are usually too thin. The common Japanese or Chinese shoe is more hygienic than these shoes which place the foot almost upon the ground, adding materially by this exposure to the danger of arthritis of the foot.

Before finishing for the present this subject of heels, the writer wishes to say that we shall be disappointed with our results if we endeavor at once to lower the heels to the physiological limit of three eighths to one half inch elevation. First, this will be notably so in those whose work necessitates standing for long hours upon hard surfaces; second, with those who have been accustomed to wearing comparatively high heels, yet have not acquired the too painful anterior foot. The heel cushion is not prepared to protect the tubercles of the calcaneus—the weight bearing surface of the heel—and Nature will set up a vigorous protest to an abrupt transfer of the greater weight to the heels. The heel cushions must

Fig. 17 C.—Well known trade shoes with outlines approaching the physiological, except the heel counter which is too long. Heel seat is insecure,—too wide, hard and not conforming to heel outline.

have a more normal heel seat, and time to accustom the parts to a function to which they are naturally adapted. Third, those who have acquired the short tendo Achillis—the muscle bound foot—will be made exceedingly uncomfortable in the low heeled shoe.

The trade has recognized the varying requirements of the pavement walker and the man in the open air, as illustrated in the outing shoes which are made either heelless or with a heel very low when compared with that of the ordinary shoe. Many persons have attributed their flat or weak foot conditions to wearing the outing shoe on a long tramp, and upon this experience condemn the low heel generally as being unphysiological. At first glance the evidence might seem to justify the conclusion. A foot that has been accustomed to a high heel, with all muscles, ligaments, and bones adjusted to that position, assuming at once the normal position in the low heeled or no heeled shoe, would surely suffer painful strain of all parts, which might result in flat or weak foot; just as any healthy exercise may be detrimental to health when practised too strenuously by unaccustomed muscles. On the other hand, a low heel is not all there is to a physiological shoe. An outing shoe may be short and narrow, precluding the possibility of normal foot action, especially of the great toe.

Another source of weakness, by disturbing the balance, appears in the broad sole which is sometimes extended to the outer side by a broad welt, carrying the centre of the shoe toward the outer side of the foot, tending to abduct the foot. In this same shoe we are apt to find the sole very much cut away on the inner side in the vicinity of the ball—the welt is too narrow. This is a glaring fault in trade shoes of otherwise good physiological lines in their uppers. This cutting away of the inner welt destroys the balance of the shoe and gives the foot a decided cant in pronation. The sole should be made with an extension to the inner side of one fourth to three eighths inch, or sufficient to make the centre of the shoe correspond with the centre of the foot, and with the greatest width at the ball to restore balance. This does not necessarily change the straight inner vamp line of Meyer.

Fig. 17 D.—Custom-made shoe. Heel having good pitch behind relieves weight of shoe and makes a neater heel. Space behind heel is very noticeable—counter not corresponding to contour of heel. Heel seat flat. *Rubber heel* relieves the shock.

Note—Examples shown in Figs. 17, A, B, C, and D have the common fault of too great length of heel behind, increasing weight of shoe and leverage upon the long arch. The heel seat is flat and a space is seen behind the individual's heel, counter not conforming to heel outline.

Another point of weakness peculiar to the ordinary shoe, especially prominent in shoes which approach the physiological outline in the upper, is to be noted in the excessive length from the breast of the heel to the ball—the long shank. This faulty construction makes such shoes prone to break down early, exaggerating the effect of the wedge heel or drag heel, and consequently tending to destroy the mechanical action of the foot. This fault may be remedied in part by giving a "full pitch heel."

Fig. 18.—Rocker sole.

The insole is generally hollowed out under the anterior metatarsal arch—the "turned" sole—and the sole curves upward at the ball—the "rocker" sole (Fig. 11). This is the shoe which, combined with the narrow toe, produces hammer toe, metatarsalgia, Morton's disease, Morton's neuralgia, etc. A shoe may be anatomically good in outline and be ruined by a bad insole or by removing it from the last before it is thoroughly dry.

The shoe must have sufficient length to accommodate the added length of the foot when bearing the weight of the body. Major Munson and the Army Shoe Board found that the soldier's foot becomes three eighths inch longer and three sixteenths inch broader when bearing the weight of the body than when at rest, and nine sixteenths inch longer and one fourth inch wider than when at rest when loaded with his marching pack of forty pounds. This indicates the necessity for wearing a longer shoe as we become stouter, and of fitting every one with shoes much longer than is apparently necessary when the foot is at rest. Foot measurements should be made while the owner is bearing all expected weight, if we would have subsequently full and free action of the anterior foot.

346 Lexington Avenue.

Stabilizing Flail Foot in Infantile Paralysis.—Edwin W. Ryerson (*American Journal of Orthopedic Surgery*, July, 1916) believes that astragalectomy and fixation of the tendons by the Gallie method should be resorted to more frequently in flail and weak feet. He modifies Gallie's method by putting the tendon high up, laying the tendon in the periosteal groove, arranging the end through a drilled hole in the bone at the upper end of the groove, and finally bringing it down and suturing it to the portion previously laid in the groove.

HERPES CORNEÆ "FEBRILIS."*

With Special Reference to Etiology,

By Samuel Theobald, M. D.,
Baltimore.

Clinical Professor of Ophthalmology, Johns Hopkins Medical School; Ophthalmic Surgeon, Johns Hopkins Hospital, and Baltimore Eye, Ear, and Throat Hospital.

Unless my experience has been exceptional, herpetic keratitis is a more common affection than is usually supposed. A habit with me, for many years, of testing the sensibility of the cornea in every case of superficial keratitis in which the etiology was in doubt may, perhaps, account in some measure for this conviction; for unquestionably the most characteristic sign of herpetic keratitis is corneal hypesthesia.[1]

It may be well to state at the outset that the term, herpetic keratitis, is used, as Fuchs employed it, in a broad sense; neuropathic keratitis, the postmalarial keratitis of Kipp, and the dendritic keratitis of Emmert being regarded simply as types of corneal herpes, the essential and common feature of these different types being a disturbance of the nerve supply of the cornea.

It does not seem that the qualifying term, *febrilis*, commonly applied to simple herpes of the cornea, is well chosen; for though herpes labialis and, perhaps, more general facial herpes not infrequently occur as an accompaniment of "colds," attended by fever, this, according to my observation, is not true of corneal herpes, which, if we except the postmalarial cases, more often than not occurs without assignable cause.

Beside the corneal hypesthesia, which is very rarely confined to the infiltrated or ulcerated areas of the cornea, as some maintain, the characteristic signs and symptoms of herpetic keratitis, commonly accepted, are the unilateral character of the affection; the diffuse and irregular form of the corneal opacities, sometimes of the dendritic type, but more often presenting a maplike appearance; the persistence of the opacities notwithstanding the fact that the substantia propria is seldom deeply involved; the obstinacy of the affection, and, not infrequently, a decided tendency to recurrence. The severe pain, which some describe, is not in my experience a usual symptom.

I have long felt that, in all probability, the primary lesion which gives rise to simple herpetic keratitis, and which explains the corneal hypesthesia, is situated in the ciliary ganglion. This lesion, it may be fairly assumed, is comparable to that which occurs in the Gasserian ganglion in herpes zoster ophthalmicus; but, since it involves only the ciliary nerves, the resultant disturbance of nutrition, the hypesthesia and the inflammatory changes which follow are necessarily confined to the eye itself, differing radically in this respect from those which are usually observed in herpes zoster ophthalmicus, where the primary lesion is in the Gasserian ganglion, and which involve, not only the eye, but the lids, the forehead, and scalp, and exceptionally the side of the nose.

I am aware that this belief is not in accord with the commonly accepted view regarding the character of the ciliary ganglion, which holds that it is purely an efferent ganglion, and that the fibres from its sensory root are not in relation with cells in the ganglion, in other words, that the ganglion is not a "station" for these sensory fibres.

If this view is correct, it is manifest that a lesion confined to the ciliary ganglion could not cause the corneal hypesthesia, and the accompanying nutritional and inflammatory changes which are characteristic of simple herpetic keratitis. But it may be safely asserted that the correctness of this conception of the nature of the ciliary ganglion has not been definitely demonstrated.

In his paper Ueber die Doppelnatur des Ganglion ciliare,[2] published, it is true, in 1881, W. Krause, as the result of research made upon rabbits, reached the conclusion that the ciliary ganglion was not a simple sympathetic ganglion, but was double in its nature, one portion of it resembling the ganglia upon the posterior roots of the spinal nerves.

More recently, Frederick Walton Carpenter, of the Harvard Laboratory of Comparative Zoology, as a result of his exhaustive study of the Development of the Oculomotor Nerve, the Ciliary Ganglion, and the Abducent Nerve in the Chick,[3] reaches a similar conclusion, at least as to the double nature of the ciliary ganglion. "The evidence," he states (p. 205), "derived from the study of both its development and its histology points to the double nature of the ciliary ganglion of the fowl," and, again, on p. 207, he says, "the larger, ventral region of the ciliary ganglion bears little resemblance to a sympathetic ganglion. The cells in it are of greater size, pericellular fibrils are not abundant, and its neuraxons are heavily medullated." He differs, however, from Krause, whom he quotes as looking "upon the [ciliary] ganglion in vertebrates lower than mammals as a homologue of a spinal ganglion," in that he considers the ciliary ganglion of the fowl "as composed of cells which fall into two categories, one being, as far as the evidence goes, in all essential respects, typically sympathetic, the other belonging to neither the sympathetic nor cerebrospinal system." On p. 144 he says: "It," the ciliary ganglion, "is almost invariably stated to be sympathetic in nature (as first suggested by Arnold), although it differs from typical sympathetic ganglia in giving origin to medullated peripheral nerves (the short ciliaries) instead of nonmedullated fibres," and on p. 150 he alludes to the investigations of Stefani, "who was led to the conclusion that the short ciliary nerves have their centres, i. e., their ganglion cells, in the ciliary ganglion, by observing the effect on the cells of that ganglion when atropine is applied to the eye."

It may be added, as not without interest, that Fuchs, whose high authority and exact knowledge we all recognize, evidently did not accept Arnold's views as to the purely sympathetic character of the

*Read before the American Ophthalmological Society, Washington, May 9, 1916.

[1] As the sensibility of the cornea differs greatly in normal eyes, we should be careful, in determining the existence of hypesthesia, to make the test upon both eyes, as a matter of control. A spill of tissue paper I have found convenient for this purpose.

[2] *Morphol. Jahrb.*, viii, p. 43.

[3] *Bulletin of the Museum of Comparative Zoology at Harvard College*, xlviii, 2, Jan., 1906.

ciliary ganglion, else he would not have made the statement: "An inflammatory affection of the trigeminus, which is located either in the trunk of the nerve itself or in the Gasserian or *ciliary ganglion*, lies at the bottom of herpes zoster ophthalmicus."[4] It would seem, then, that there is no well founded anatomical or physiological objection to my belief that the primary lesion responsible for simple herpetic keratitis is situated in the ciliary ganglion.

Opposed to the view that the lesion may be in the Gasserian ganglion, it may be said that while simple herpes of the cornea, as has been stated before, is of relatively frequent occurrence, herpes zoster ophthalmicus, which as commonly observed we know *is* due to disease of the Gasserian ganglion, is a rare affection; and this contrast is emphasized by the fact that the picture which the latter presents is so typical that an error in diagnosis can scarcely be made, even by a tyro, while it is not improbable that a considerable number of cases of simple herpetic keratitis are not recognized as such, even by those who cannot be regarded as novices. Furthermore, if the primary lesion is in the Gasserian ganglion, it is difficult to explain why the peripheral manifestations should be confined to the cornea, and why this peculiar sort of lesion should occur so much more frequently than the more extensive pathological condition which gives rise to the usual type of herpes zoster ophthalmicus.

The only other explanation of the etiology of simple herpetic keratitis would seem to be that the ciliary nerves, in their short course from the ganglion to the posterior pole of the eyeball, are primarily involved, which, to say the least, does not appear to be a probable hypothesis.

As Dr. W. H. Howell, head of the physiological department, and Dr. Florence R. Sabin, of the anatomical department, of the Johns Hopkins Medical School—both of whom have afforded me helpful assistance in the preparation of this paper—feel that by the employment of modern methods of research it should be possible to clear up the present uncertainty regarding the true character of the ciliary ganglion, I am not without hope, if the right man can be found to undertake the exact and painstaking work required, that under the supervision of one or the other this much to be desired end may be attained.

TREATMENT.

As to the treatment of herpetic keratitis, I may say that the local remedies which I have found most useful are holocaine and atropine, and that not infrequently one, sometimes both of these are supplemented by instillations of dionin.

Holocaine is usually my first choice, to avoid the inconvenience of mydriasis, and it is employed in a one grain—if there is much ciliary irritation in a two grain—to the ounce solution, with the addition always of boric acid, ten grains to the ounce. If the response to this is not satisfactory, atropine—two to four grains to the ounce, with the addition of boric acid in the strength just mentioned—is substituted. Not infrequently, as has been indicated, both of these agents are employed, and, if the keratitis proves intractable, dionin, in five per cent. solution, applied twice or thrice daily, in conjunction with one or the other, possibly with both, is tried.

The constitutional remedies in which I have learned to place confidence, are quinine, in generous doses, and potassium iodide, each of which is given with the idea that I am attacking the primary lesion supposedly in the ciliary ganglion. The former, commonly first prescribed, is given in doses sufficient to produce some cinchonism, usually three grains, four times a day. If the response to this, after a fair trial, is not satisfactory, potassium iodide in moderate doses, usually ten grains three times a day, is given instead. Arsenic, which some think useful, I have not found as efficacious as the two drugs mentioned.

A rapid subsidence of the keratitis is seldom observed, and we should be prepared and, what is more important, should prepare the patient for a somewhat tedious recovery. The first observed evidences of improvement, as generally recognized, are a diminution of the ciliary irritation—the photophobia, lacrymation, and blepharospasm—and a lessening of the conjunctival injection, which is only exceptionally very pronounced at any stage, to be followed later by a gradual change for the better in the condition of the cornea—the restoration of lost tissue, which is seldom considerable, the reformation of the epithelium, and, last of all, the disappearance of the opacities, which, not very infrequently, is incomplete, and of the hypesthesia, which is commonly long delayed, and which, I am inclined to believe, is also, in some instances, incomplete.

Cathedral and Howard Streets.

THE MANAGEMENT OF THE COMPLICATIONS OF PREGNANCY.

By John A. McGlinn, A. B., M. D.,
Philadelphia.

It is impossible in the space allotted me to do more than cover superficially a few of the complications of pregnancy. Instead of selecting a number of subjects, I shall consider a few that I have met recently in my own practice.

Retrodisplaced pregnant uterus. Retrodisplacement occurs comparatively infrequently in the nulliparous. When it is present it is frequently the cause of sterility. This displacement is common in the multiparous woman and, while sterility may result, nevertheless conception is rarely interfered with. If a woman with this displacement does become pregnant, abortion is likely to result. If abortion does not result, the uterus may become incarcerated behind the promontory of the sacrum, or spontaneous replacement of the uterus may occur. If incarceration occurs, a rupture of the uterus is likely to result or sacculation with displacement of the cervix may supervene so that it becomes impossible for normal labor to take place.

Unless the displacement is associated with adhesions, few symptoms are present until the uterus is enlarged enough to fill the pelvis and press on adjacent organs. Adhesions are rare in these cases, for the reason that if adhesions were present the

pathological condition of the uterine annexa would be such that pregnancy could not occur.

The bladder is about the first organ to give rise to symptoms. As the fundus of the uterus enlarges, the cervix is pressed up under the symphysis and the neck of the bladder is impinged upon. The bladder is also displaced upward and backward. The impingement on, and the displacement of the bladder cause irritability and frequent desire to urinate is a common result. In some cases the bladder cannot empty itself and the constant overflow of retained urine occurs. If the bladder does not become distended, it shows a distinct tumor above the symphysis and may be mistaken for the fundus of the uterus or a cystic tumor and complicate the diagnosis. It is advisable, therefore, to emphasize the cardinal rule, "Always catheterize the bladder before making a diagnosis in the case of a pelvic abdominal tumor." In addition to the bladder symptoms, pelvic pain, the feeling of fullness in the pelvis, and rectal irritability are constant symptoms. It is well to bear in mind that pressure on the ureters may occur and be followed by uremia.

In the management of these cases, special emphasis should be laid on prophylaxis. The care of a case of pregnancy is not finished with the delivery. Every woman after labor should be examined at the end of the puerperium to note the condition of her pelvic organs. If a displacement is found, the uterus should be replaced and held in position with a properly fitting pessary. These are the cases in which a pessary will cure a displacement. Of course, the treatment presupposes an earlier examination with the correction of any laceration of the birth canal which may have been present.

The management of an actual case depends on when it is seen and the conditions present. Perhaps this phase of the treatment can best be illustrated by the recital of a few cases.

Two cases recently delivered, one a primipara, the other a secundipara, came under my observation in the second month of pregnancy. A routine examination disclosed the uterus in each case to be caught behind the symphysis before incarceration or symptoms developed. Both uteri were replaced by manual manipulation aided by the knee chest position. After replacement, pessaries were inserted and the uteri held in correct position until pregnancy had reached the fourth month, and the uteri were well out of the pelvis, with no chance of the displacement recurring. Pregnancy advanced normally and both patients were delivered at term. Both cases exhibited an aggravated type of vomiting which cleared up immediately with the correction of the displacement. It is well to bear in mind that displacement of the pregnant uterus is a common cause of the aggravated type of vomiting. I cannot too strongly urge the advisability of a routine pelvic examination in the early months of pregnancy.

Within the past year I have had two cases of incarcerated pregnant uterus, one in a primipara at five months, and one in a secundipara at four months. It was impossible in these cases to replace the uterus manually, even under anesthesia. In both cases the abdomen was opened and the uterus freed from incarceration by internal manipulation. The primipara at five months miscarried at the end of a week. The secundipara was delivered at term of a living child. After operation both patients received large doses of opium.

Other forms of treatment are advised, abortion and rupture of the membranes. Abortion is not easy to perform owing to the inaccessible position of the cervix. Posterior vaginal hysterectomy has been advocated by De Lee to overcome this difficulty. The idea of rupture of the membranes is to reduce the size of the uterus so that it can be replaced and assumes the possibility of the membrane healing and pregnancy continuing. Of course, this is an unlikely sequence. Personally, I am opposed to the last two measures unless laparotomy is positively contraindicated.

Ovarian cyst. Ovarian cysts of large size are infrequent complications of pregnancy. If present, they are always a serious complication. It is impossible to know in any safe and definite way the contents of an ovarian cyst before removal. Associated with pregnancy there is always the danger of direct rupture or rupture after twisting of the pedicle with discharge of the contents into the peritoneal cavity. If the contents happen to be septic, malignant, or irritating, death is likely to occur. Again, a portion of the cyst is practically always pelvic, so that the cervix is displaced and the superior strait is encroached upon by the growth, and if pregnancy goes to term, obstructed labor is likely to result. Obstetricians and gynecologists, on account of the dangers of this complication, are practically unanimous that an ovarian cyst complicating pregnancy should be removed as soon as diagnosed. It is advisable again to counsel catheterization of the bladder before operating to remove a cyst. I have seen several "ovarian cysts" cured by the use of a catheter. I have had two ovarian cysts complicating pregnancy, one with a twisted pedicle. Both were removed by section, and both patients went to term and were delivered of living babies.

Right sided abdominal pain is a frequent and distressing complication of pregnancy. It is almost always diagnosed as appendicitis, but it must be borne in mind that infection of the right urinary tract is a more frequent cause than the appendix. There is little similarity in the symptoms and physical signs of the two conditions, except the site of the pain. In pyelitis and ureteritis the pain usually radiates toward the lumbar region, while in appendicitis the pain is more apt to radiate toward the umbilicus or ensiform. In pyelitis and ureteritis, recurring chills are the rule and gastrointestinal symptoms are absent, whereas in appendicitis chilis are absent as a rule and gastrointestinal symptoms, nausea and vomiting are more or less constant. Infections of the urinary tract have associated bladder symptoms, which are negative in appendicular infections. In pyelitis and ureteritis, rigidity of the abdominal wall is absent and the greatest amount of tenderness is over the kidney. In appendicitis the rigidity of the abdomen is a constant finding and the greatest tenderness is found over the appendix. The urine in kidney and ureter infections shows pus and bacteria. In appendicitis, while bacteriuria is common, pus is usually absent.

Autopsies on pregnant women have shown that torsion of the right ureter with distention and retention of urine is a frequent finding. The retention of the urine in the ureter and pelvis of the kidney is a common predisposing factor of infection. Infection of the retained urine frequently takes place, and the colon bacillus is the common infecting organism.

The management of these cases is as follows: Place the woman at rest in bed and have her assume the knee chest position frequently during the day. The diet should consist essentially of milk and water, and buttermilk is to be preferred to sweet milk. Hexamethylenamine in large doses should be given, as much as sixty grains a day. If there is intolerance to this drug, salol or methylene blue may be substituted. If this treatment fails, a cure can usually be obtained by inserting a catheter into the ureter and washing out the ureter and pelvis of the kidney with some nonirritating and mild antiseptic solution. While this is a satisfactory treatment, it is frequently difficult and dangerous. It should be remembered that the ureter is usually distorted with the walls thinned out and there is grave danger of perforation of the ureter with the catheter. It has been advised to empty the uterus in these cases, but while I have had many cases I have yet to see one in which I deemed this procedure advisable. De Lee advises against the use of bacterial vaccines while the uterus is still gravid. When the infective agent has been the colon bacillus, I have found an autogenous vaccine the most satisfactory form of treatment and have never seen untoward results. It is my belief that if the symptoms of kidney and ureteral infection do not clear up under the use of hexamethylenamine or vaccines, the case is probably one of kidney or ureteral calculi, and an x ray study of the case should be made. This is simply an expression of an opinion, not based on experience. All the cases that I have had in my own practice have cleared up under treatment. I believe the great thing in the treatment is the extra large doses of hexamethylenamine. I have failed to obtain satisfactory results when the drug has been administered in the usual doses.

Appendicitis is a most formidable complication of pregnancy. It is not necessary to speak specifically of the diagnosis, as I have already referred to it in the differential diagnosis of pyelitis and ureteritis. The salvation of a patient with this complication depends on early recognition and immediate operation. Appendicitis cannot be cured by an ice bag and a dose of salts, but patients can be killed by this treatment. Delayed operation is particularly dangerous in pregnancy at any time after the uterus has become an abdominal organ, because the uterus is likely to form one wall of the abscess. In these cases, owing to the necessary manipulation and the constant irritation of the drain, abortion is likely to occur with the breaking down of protecting adhesions to be followed by diffuse peritonitis and almost certain death.

I have always been impressed by the frequency of abortion, even after a simple appendicectomy where the uterus has not been handled at all.

I have removed ovarian tumors complicating pregnancy and have done myomectomy on a gravid uterus and gestation has not been disturbed, but a large percentage of my appendix cases have resulted in abortion. I have never been able to arrive at a satisfactory explanation of this phenomenon. Of course, in advanced pregnancy the abdominal walls retract, once incised, and the incision can be closed only with considerable tension. The pressure and irritation of the contracted abdominal walls would cause the uterus to contract and produce an abortion, but this factor would hold no matter for what reason the abdomen had been opened. In late pregnancy, when the appendix is displaced and a large incision is necessary to locate and remove it, it is next to impossible to close the incision. In some cases it is necessary to do a Cæsarean section and empty the uterus before the incision can be closed satisfactorily. The cardinal rule in the management of appendicitis complicating pregnancy is early diagnosis and immediate operation.

Intestinal obstruction. I have had two cases of intestinal obstruction complicating pregnancy. One was due to a volvulus in the small bowel and the other to a growth of the descending colon. The first patient recovered from the operation, went to term, and was delivered of a living baby. In the second case a portion of the colon was resected and an end to end anastomosis made. The woman miscarried about two weeks after operation. The pathological report of the growth removed at operation was that it was benign. The patient turned up about a year later at another clinic with general carcinomatosis of the peritoneal cavity.

The management of intestinal obstruction complicating pregnancy is the same as in cases independent of pregnancy. The operation is complicated by the presence of pregnancy and there is always the possibility and dangers of postoperative abortion.

Fibroid tumors of uterus. I have recently had under observation two cases of pregnancy complicated by fibroids of the uterus. Both were primiparæ pregnant five months. In one case the tumor was situated in the posterior wall of the uterus at the level of the internal os. At operation it was found inadvisable to attempt a myomectomy. The only alternatives were hysterectomy or noninterference. This latter course was adopted for the reason that the patient was a primipara, exceedingly anxious for a child. To have performed hysterectomy would have destroyed the child she was carrying and of course render her sterile. The abdomen was closed with the expectation of pregnancy continuing to be followed by Cæsarean section at term, Fortunately the patient aborted, two weeks later, of an anencephalic monster. This case will be the subject of a separate report.

In the other patient, the tumor was situated on the lateral wall of the uterus, and displaced the cervix to one side. The growth, which was the size of an orange, was removed by myomectomy. Pregnancy has continued normally since the operation and the patient expects to be delivered next month.

There are several important points to be remembered in connection with fibroids complicating pregnancy. The first is that as a matter of fact the tumors are so situated that as a rule they do not ob-

struct labor. Even when the tumor is situated low in the pelvis, it frequently recedes beyond the presenting part. The second is that myomectomy is a comparatively safe and successful operation in properly selected cases. The entire subject of fibroids as a complication of pregnancy is too complex for detailed consideration here. The lesson I wish to impress from the recital of two of my recent cases is that there are modes of treatment other than hysterectomy.

Atresia and septa of the vagina. I have had three cases occur in this category. One case was particularly interesting. A patient was having electrical treatment for a pelvic condition, and pregnancy was not recognized. During one of the treatments she accidentally brushed against the rheostat and the full force of current was turned on, which resulted in a severe burn of the upper portion of the vagina. The burn healed with obliteration of the vaginal vault. I saw her first when she was six months pregnant. The upper portion of the vagina was closed off and the cervix was not approachable. The patient was allowed to go near term, when she was delivered by abdominal Cæsarean section. Then the uterus was opened, a finger was carried through the cervix and the vaginal obstruction was found to be so thick that it was my judgment that an opening through it could not be maintained to provide for menstruation, and the operation was completed by a hysterectomy.

The other two cases were of septa of the vagina, one longitudinal associated with a bifid uterus. The septum in this case was removed and the patient delivered without difficulty several months later. The other case was of a transverse septum in a multipara. The septum was not congenital and was probably inflammatory in origin. In this case the septum was removed and labor was uncomplicated.

Congenital stenosis and septa of the vagina sometimes offer an insuperable bar to normal labor. The great danger is injury to the bladder and rectum, followed by hemorrhage and infection. Good judgment must be exercised in handling cases of this character, and in many of them abdominal Cæsarean section is the best method of delivery.

Acute infections of the vagina and vulva. Postconception gonorrheal infection of the vagina and vulva is not an infrequent complication of pregnancy. Every pregnant woman has more or less discharge, but if it is innocuous it is not profuse or irritating. If a pregnant woman complains of a profuse or irritating discharge, suspicion should be immediately directed toward the possibility of gonorrhea and measures taken to arrive at a correct diagnosis. If gonorrhea is diagnosed, treatment should be immediately instituted to eradicate it before labor sets in. There is not only danger to the mother from the standpoint of puerperal infection, but the danger of ophthalmia neonatorum must be considered. It is not my purpose at this time to consider the treatment of acute gonorrhea in the female. Just this much in passing—I have found the yeast treatment most efficacious in this disease. It should be emphasized that though the disease is apparently cured and there have been repeated negative smears for gonococci, we cannot be sure that the disease is entirely eradicated. Gonococci may be present deep in the tissues and set free by the traumatism of labor and their virulence exacerbated. In these cases it is not only justifiable but advisable to give a copious antiseptic vaginal douche at the beginning of labor, and to continue the douche and to observe the utmost vulvar cleanliness during the puerperium. The instillation of silver into the child's eyes must not be neglected, and I believe, in addition to this in a case with a frank gonorrheal history, that the eyes should be irrigated frequently during the first two weeks of life and also that the instillation of silver should be repeated on the third day. I had one such case where dependence was placed entirely upon the usual treatment, and ophthalmia developed ten days later. Fortunately it was a mild infection and yielded promptly to treatment.

If infection occurs in the vulvovaginal glands, temporizing treatment should not be attempted. I have had such a case within the past week. In this case the entire gland was eradicated and this is the treatment which should always be followed.

I have purposely omitted in this short paper any reference to toxemias of pregnancy because I have already had the privilege of presenting this subject to the profession and also because it is so important that it should not be considered in connection with other subjects. I cannot close this paper, however, without referring to one phase of this subject. Those of us who are in close touch with obstetrical literature and with lay writing as well and who are familiar with the thoughts of some of the leaders of the profession, and who see cases in consultation with general practitioners, cannot but be alarmed at the growing tendency to hold in little sacredness the life of the unborn child. When presumably reputable doctors will advise and well known journals will print the advice to eliminate the criminal abortionist by the surgeon taking over their work of crime, so as to eliminate the maternal dangers, then I think it time for the profession to arise in its might and protest against violation of the sacredness of the medical profession. The child in utero has a right that none can gainsay and the question of therapeutic abortion cannot be solved lightly. And yet hardly a day passes that we are not asked, not to see and study the case, but to put the patient in the hospital and abort her immediately just because vomiting is aggravated. As a matter of fact, very few cases of toxemia of early pregnancy call for the termination of gestation. The majority of such cases are not toxic at all, and the condition is cured under proper treatment. Even when the condition is toxic, the majority of cases can be tided over to term or at least to viability with absolute safety to the mother. This question is not only a moral one, but it is a great economic one. America needs her children, and it is just as important to conserve their life in utero as it is after they are born.

113 South Twentieth Street.

Nasal Accessory Sinuses.—C. A. Veasey (*Jour. Ophth. and Otol.*, April, 1916) states that many toxemias of the gastrointestinal tract, as well as of other portions of the body, are due to infections originating in the nasal accessory sinuses.

SYPHILIS AND TUBERCULOSIS IN THE SAME LUNG.

By Robert A. Keilty, M. D.,
Philadelphia.
(*From the McManes Laboratory of Pathology, University of Pennsylvania.*)

Syphilis in the form of chronic interstitial pneumonitis, with bronchiectasis and tuberculosis in the form of miliary and conglomerate tubercles with caseation, were present in the left lung and tuberculosis almost alone in the right lung. I am indebted for the following history and permission to report the case to Dr. David Riesman and his staff at the Philadelphia General Hospital. The following history was obtained:

Case. L. B., a male, colored, laborer, aged twenty-three years, was admitted February 1, 1912, and died February 29, 1912. He complained of cough, expectoration, and dyspnea, with pain on the left side and general weakness. Three months before his admission, his trouble began with cough; three weeks before admission, the cough became worse, with a diffuse expectoration and pain on the left side. With this there was failing strength and loss of weight, but no sweats. Upon admission his temperature was 100.3° F., pulse 84, and respirations 25; a profuse, yellow, foul expectoration; the sputum separated into two layers, the upper solid and the lower fluid. This showed elastic tissue, débris, and many organisms with negative tubercle bacilli.

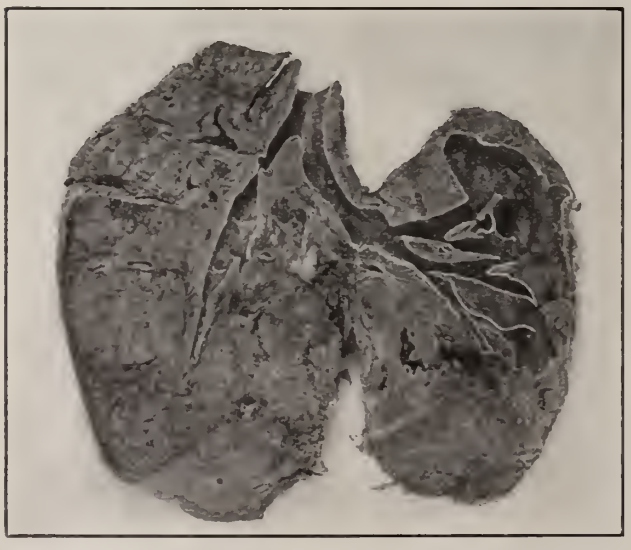

Fig. 1.—An anterior view of the cross section of both lungs without excision from the bronchi. The left shows the cylindrical dilatation of the larger branches of the bronchi terminating in cavities. The tuberculous process is well seen on the right side.

Physical examination showed an anemic chest, with dullness, flatness, and friction posteriorly on the left. Bronchial breathing, bronchophony, pectoriloquy, and egophony were present below the left scapula. The right chest was hyperresonant, with infiltration at the right apex anteriorly and good resonance posteriorly. A diagnosis of pulmonary gangrene was made, the patient was transferred to the surgical ward, and operated upon on February 17, 1912. An incision was made in the sixth interspace in the posterior axillary line on the left. The exploratory needle showed no pus or fluid; digital examination palpated pleural tuberculous nodules. The patient improved somewhat, but grew weaker and died. The urine analysis showed a small amount of albumin and a few casts. The blood showed a moderate secondary anemia, with a leucocytosis of 24,000 and 10,000. Temperature fluctuation was around 103° F., pulse about 120, and respirations never over 35.

Autopsy findings: An emaciated adult black male, weighed about 108 pounds; the right arm had been amputated and scars were present on the shins; the meatus of the penis presented a firm contracted scar.

The right thorax contained 100 c. c. of fluid, with patchy fibrinous adhesions. The left had no fluid but a fibrinopurulent exudate obliterating the cavity in places. The parietal and visceral layers of the pleura were decidedly thickened and adherent to the pericardium. The left lung was firm throughout, crepitated at the apex, and the pleural surface showed an extensive fibrinopurulent exudate easily scraped off, leaving a bluish surface with white fibrous points. On the lung surface corresponding to the operative incision was a cavity three cm. in diameter, with rough and jagged edges. Upon section the organ cut with resistance. The root, especially running to the lower lobe, showed branching white lines much like the lines of a palm leaf fan. This was fibrous in character. The left bronchus with its larger branches was dilated and the tree opened into two large cavities, one in the upper and one in the lower lobe. These cavities were fairly regular, had smooth walls with many dilated bronchioles opening into them. The content was a moist, coarsely granular, inspissated material. Where the lung was not involved in this latter process, there were small, irregular, caseous areas, not very numerous, however. In the lower part of the lower lobe there was a small, irregular cavity, which did not communicate with the bronchi, but which was irregular in outline and presented a ragged wall. The right lung measured twenty-five by ten by ten cm., stood up firmly, and its surface was pale yellow and less markedly fibrous. The larger branches of the bronchi in this lung were dilated without the formation of cavity. The fanlike extension of fibrous tissue was not so apparent. The cut surface was moist, red, and granular, with a conglomerate caseous involvement which affected all lobes.

For the microscopical examination nine sections of lung were made. Four of these were stained by the Leviditti method, one for the tubercle bacillus, and four with hemotoxylin and eosin. Two small groups of spirochetes were found in the fibrous tissue of the root of the left lung. This was confirmed by Dr. A. J. Smith. The tubercle bacilli were scattered, but easily demonstrable. One slide from the right lung showed a general congestion and some dilatation of the alveolar spaces. There were numerous tubercles, miliary, conglomerate, and caseous. A section from the bronchiectatic cavity of the left lung showed a thick fibrous wall with numerous new bloodvessels forming. In the periphery of the wall were seen nodules which had a central necrotic area, surrounded by a lymphoid zone and irregular endothelioid proliferation. There was some question whether these were miliary gummata or tubercles. Other slides showed fibrinous exudate on the surface of the pleura, congestion of alveolar walls, and numerous small miliary tubercles. Where the fibrosis was marked, the epithelial cells of the alveolar walls were numerous and showed a metaplasia into a squamous type of cell.

CONCLUSION.

In the summary of this case the following interesting facts are presented: A colored male, aged twenty-three years, shows a progressive loss of weight, with cough, dyspnea, and a profuse fetid expectoration of three weeks' duration (seven weeks before death). The physical signs point to infiltration and cavity in the lower left lung, with infiltration in the right. In the absence of tubercle bacilli in the sputum and with a history of a rapid course, a diagnosis of pulmonary gangrene led to operation, when the tuberculous nature of the case was revealed.

At death the autopsy demonstrated the left lung to be the seat of a cylindrical dilatation of the bronchi, with two fairly large bronchiectatic cavities and a generalized overgrowth of fibrous tissue. Presumably engrafted upon this, or possibly primarily present and secondarily stimulated by the syphilitic process, a tuberculous process of miliary and

conglomerate tubercles with caseation was present. Microscopically some of these tubercles closely resembled gummata. The tubercle bacillus and Spirochæta pallida were demonstrable in appropriately stained preparations.

REMOVAL OF AN INTERSTITIAL FIBROMYOMA.

Removal Due to Hemorrhage, Immediately Following High Forceps and Manual Placental Delivery,

By John J. Sheehey, M. D.,
New York.

This is a report of a unique case of extraction of an intramural fibromyoma situated in the lower uterine segment, at full term, immediately after manual delivery of the placenta, on account of hemorrhage.

Case. In an emergency I was called to attend Mrs. M., aged thirty-six years, multipara, three children, two years apart, first child ten years ago, second stillborn, each a forceps delivery. She had been twelve hours in labor;

Fig.—Doctor Sheehey's intrauterine myoma.

the os well dilated and quite dilatable; head unengaged, L. O. A., pains short, sharp, exhausting; no seeming progress; violent uterine contractions. Three hours after examination, one c. c. of pituitrin was given hypodermically, and in due time chloroform, less than an ounce, to the surgical degree; high forceps were adjusted with the usual difficulty, and delivery accomplished. The placenta which detached itself was retained, but was readily extracted.

In extracting the placenta an intrauterine myoma was discovered in the lower segment of the uterus. Hemorrhage occurred immediately after placental delivery. The Credé method failed, as did bimanual manipulation. The hand was introduced to the fundus and a tumor about the size of an orange, hard and lobular, was gradually enucleated. The hand was pushed high up, anteriorly above the tumor and with some difficulty the fingers gradually separated the tumor from the muscular tissue and peritoneal covering; as this was done, the uterine covering underwent prolapse through the uterine wall and remained so until contractions of uterus took place, when it resumed its normal position. The hemorrhage was immediately controlled. No sepsis or other complication followed.

The fibromyoma measured 6.32 by 6.08 by 20.32 cm.

The pathological examination of the tumor was made by Dr. Archibald Murray, of the Hoagland Laboratory.

Fibromyoma of the uterus causing hemorrhage, during the third stage of labor, demands quick judgment and immediate action. Any extensive operation under such conditions is dangerous. In studying the case it appears that the fibroid prevented regular uterine contractions, but the placenta detached itself, and was held in the uterus by the size and position of the tumor.

A careful search through the surgeon general's office at Washington did not show a similar case. Fibrinous tumors have been reported that had been removed, and some submucous ones that had been crushed by forceps delivery. It is the consensus that sepsis follows the removal per vaginam of a fibromyoma after forceps and manual placental delivery at term. Sepsis should not follow. It did not supervene here, nor is there any reason why sepsis should occur if the procedure has been conducted properly.

THE NEPHRITIC TOXEMIA OF PREGNANCY.

Etiology and Treatment,

By Arnold H. May, M. D.,
Buffalo, N. Y.

The great group of the toxemias of pregnancy consist principally of the conditions known as eclampsia and preeclamptic state, pernicious vomiting of pregnancy, and the nephritic toxemia of pregnancy. The last condition occurs most frequently during the latter half of gestation; and may or may not follow upon an already impaired kidney. It may be acute or chronic, and it is a significant fact that it may occur about the same time in each subsequent pregnancy. In all these cases it is important to know the condition of the kidney, and particularly the way this organ reacts at different periods of pregnancy. In most instances the higher degree of function of the kidneys during pregnancy, in the excretion of added metabolic products, will produce a condition in which a diversity of factors may quickly effect the histological structures.

In pregnancy there is a gradual progressive abdominal increase, so that at the fourth month the uterus is no longer a pelvic organ; and with increase in growth, it almost reaches the liver. The uterus is, moreover, movable above and attached below to the cervix. In the erect position, during the latter part of pregnancy, the anterior abdominal walls form the principal support for the organ, whereas in the recumbent position the uterus lies upon the vertebral column. After the fourth month, the organ increases more rapidly in length than in breadth. With the increase in size of the uterus, toward the latter half of pregnancy, the woman upon reclining assumes the dorsal, and more rarely the lateral position. This constant lying on the back, a position most often assumed by the pregnant woman, results in pressure, intermittent or constant, upon the kidneys or their excretory ap-

paratus, the pelves, and the ureters. The abdominal position in the recumbent state is untenable in the latter half of pregnancy. In the course of the exertion of this pressure, there occurs a damming

Fig. 1.—A, rubber sheet; B, holes to regulate depression of sheet.

back of the urinary stream, which may be only transient during that period in which the patient is in the recumbent position, and is relieved when the upright, or less often, when the lateral position is assumed. As was said, this damming back of the stream may be transient, but when the pregnant woman is ill, may be constant, owing to the fact that she then assumes the recumbent position. The increased intraureteral pressure caused by the damming back of the urinary stream causes an increased strain, or produces trauma to the histological parenchyma of the kidneys. This trauma, however slight or great, depending upon its duration, produces a greater reaction than usual, because of the increased strain upon the excretory function of the kidney during pregnancy. As a result of this strain, not necessarily a hydronephrosis, but the entire kidney function may be distorted, resulting in a pathological condition productive of the clinical picture of the nephritic toxemia of pregnancy. Again it is apparent how naturally these

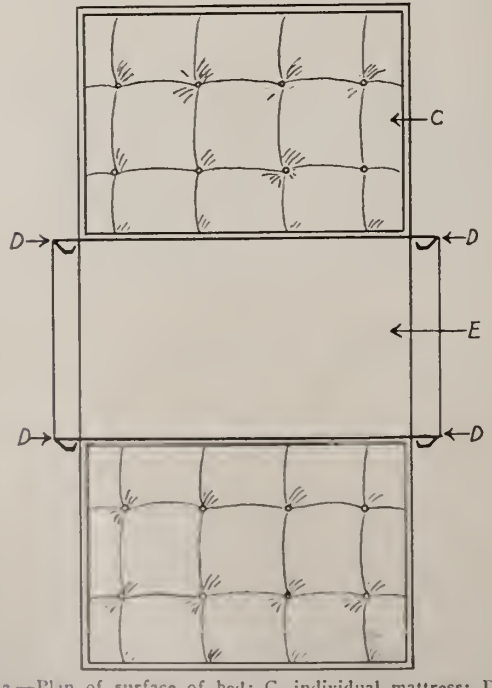

Fig. 2.—Plan of surface of bed; C, individual mattress; D, bars for the attachment of holes in sheet; E, space for rubber sheet. A bed of this character can be improvised.

women whose kidneys are impaired previously to pregnancy by disease are more likely to succumb to this trauma, and suffer the nephritic toxemia of pregnancy. The increasing demands upon the kidneys during pregnancy may then be a predisposing, but not a primary factor in the causation of this condition.

The etiology of this condition, then, may be a growing organ variously weighted depending upon child development, which presses upon the renal excretory apparatus. With this in mind the writer has suggested a mode of treatment. Particularly is this method advocated, when it is remembered that in this condition the patient lies in bed; semiconscious, edematous, breathing stertorously, and yet in the dorsal position; the kidney in such a manner sustains the original shock, which was primarily responsible for the existing condition. The writer believes that in these cases where there is a predisposition to this disease, which can be determined by the condition of the kidneys before pregnancy, this treatment should be used as a matter of prophylaxis; where the disease already exists, it constitutes an adjuvant factor of the greatest importance in its treatment. The idea is to permit the patient to assume the recumbent position, but simultaneously to remove all weight (pressure) from the kidney excretory apparatus. This can be accomplished by the use of a special bed, which can be improvised for private or hospital use. The bed, as roughly shown in Fig. 2, consists of a head piece and foot piece, separated by an area of about two feet, each part having (head and foot) a separate spring and mattress. Between these parts the bed is open, except for an adjustable sling made either of rubber or cloth, preferably the former. The rubber sheet (Fig. 1) is sufficiently long so that it can be depressed to various degrees to accommodate the protuberant abdomen. The bed may be of any desired height. The patient assumes the recumbent position with the face downward. The protuberant abdomen is supported sufficiently by the sling to withstand great pressure upon the anterior abdominal wall, but at the same time to relieve pressure exerted upon the posterior abdominal wall, the kidneys, and their excretory apparatus. By this means a great degree of comfort may be assured the patient, the anterior abdominal wall is properly supported, while at the same time all pressure is withdrawn from the kidney; the shock resulting from such pressure is thus averted. This mode of treatment may be applied both as a prophylactic measure, where there is a predisposition to the disease, and as an important adjuvant measure in the treatment of the condition. Its application to the preeclamptic and eclamptic conditions, where there is such a profound kidney disturbance, will be determined by clinical observation of its use.

177 Walnut Street.

Pituitary Extract in Adiposis dolorosa.—Charles M. Nice (*Medical Record*, July 8, 1916) describes a case in a girl of twenty-two years, five feet and three inches in height, who weighed 262 pounds. No improvement followed the use of thyroid extract, but daily hypodermic use of pituitary extract produced rapid and continuous progress, with great improvement in the mental condition, and walking was rendered possible within two weeks, although the patient had been in bed for six months.

THE PATHOGENESIS OF PSORIASIS.

A Clinical Study; The Effect of Emetine Hydrochloride,

By Abner H. Cook, M. D.,
Hot Springs, Ark.,
Associate Visiting Physician, Leo N. Levi Memorial Hospital.

In reviewing the recent literature on psoriasis the articles found most instructive are those of Fox (1) and Holland (2) on the treatment, and on the etiology Schamberg, Ringer, Raiziss, Kolmer (3) researches, and Menzer's (4) article on psoriasis as a symptom of constitutional bacterial disease. Holland treats with a vaccine and Fox with autogenous serum, and the observations of Menzer suggest the presence in the body of some infecting organism, whereas the work of Schamberg, Ringer, Raiziss, and Kolmer indicates that the disease is due to disturbed protein metabolism.

It is interesting to note that the theory of a neuropathogenesis of psoriasis seems to have been abandoned; nothing can be found in the recent literature to support the theory, and recent research workers do not mention it. Also, careful searches for a specific organism have been made with negative results; especially painstaking were those of Schamberg, Ringer, Raiziss, and Kolmer.

The cases constituting the material for this study are ten in number, all in males, aged from twenty-two to forty-one years, whose vocations varied from laborer to banker. The skin disease in each case was unquestionably psoriasis; where there was a doubt in the diagnosis, the case was not studied. The study was begun by accident, curiosity having been excited by the following case:

Case I. Male, aged thirty-nine years, weight 129 pounds, married, banker, first came under my care, February 3, 1913, suffering from a severe arthritis, involving both knees and the sixth, seventh, eighth, and ninth thoracic vertebral articulations. Had had several previous attacks of arthritis, the last in the winter of 1911. The onset of the present attacks of arthritis dated from December 24, 1912. The knee joints became suddenly inflamed, and later the vertebral articulations became involved. There was fever from the onset; the patient had lost about thirty pounds in weight.

Present condition: Patient was a thin, sallow, emaciated man, whose expression denoted suffering; temperature 102° F. The thorax and abdomen were negative; particular attention was paid to the lungs, as the possibility of tuberculosis was imminent. A dark red psoriatic eruption was present over both elbows and extended down over the crest of the ulnas, a patch the size of the palm of the hand was present over the sternum, a circinate patch about three and a half inches in diameter was situated above the right external malleolus, and several small patches were scattered over the anterior surfaces of both thighs. The rash had been present for several years; at times almost totally disappearing, only to flare up with the next attack of arthritis. The von Pirquet, serum, Wassermann, sputum, and urinary examinations were all negative. The blood was: Hemoglobin fifty per cent., white cells 9,200, red corpuscles 3,450,000, color index 0.7.

Treatment: Hot Springs baths, rheumatism and mixed infection phylacogen, salicylates, colchicum, iodides, and the whole list of empiric remedies that is recommended as valuable in arthritis, was exhausted. The patient grew steadily worse, pain more severe, weight decreased twelve pounds, and the fever continued; therefore, he left Hot Springs, March 28, 1913.

On February 8, 1915, the patient again presented himself, giving a history of complete recovery from the attack of 1913, during the summer of that year. The psoriatic eruption had almost completely disappeared during the intermission. There was no attack in the winter of 1913-14, but during the first week in January, 1915, arthritic symptoms reappeared. The onset was insidious, no fever developed, the same joints were involved as before, and the psoriasis covered about the same areas. The examination disclosed the same conditions as before, except that the joint involvement was not nearly so severe; he had lost but ten pounds in weight, had no rise of temperature, and a severe pyorrhœa alveolaris, involving an area from the lower left lateral incisor to the lower right premolar tooth, was discovered; the patient stated that this condition had existed for years. Endamœbia buccalis was present.

Administration of one half grain of emetine hydrochloride by hypodermic injection was begun February 10th and continued daily for seven days, after which one week of rest was allowed. On February 23d, there was but little pus; two endamebas were found in three slides, and there was slight improvement in the arthritis. On February 24th emetine was again instituted as before and continued for seven days, then followed another week of rest. An examination, on March 9th, revealed a complete recovery from pyorrhea, no pus or endamebas were present, the gums were beginning to assume a firm and healthy appearance, and the teeth to tighten up. The joints had resumed their normal shape and size, and there was but little pain upon pressure or movement. The patient called my attention to the fact that the psoriasis had begun to fade. The third treatment with emetine, the same as the two previous, was begun on March 10th and continued until March 16th. On March 31st the patient left for home completely relieved of his pyorrhea, rheumatism, and psoriasis. During the entire treatment he had used as a wash for the gums, the fluid extract of ipecac.

That there was an etiological connection, in this case, between the pyorrhœa alveolaris, arthritis, and psoriasis is evident. The relationship between arthritis and pyorrhœa alveolaris, as well as other infections, has been established; also the frequent occurrence of psoriasis in patients suffering from arthritis has been noted by many competent observers. With these facts known, the points for study suggested by this case were: 1, The relationship between psoriasis and pyorrhœa alveolaris; 2, the role of emetine hydrochloride as a remedy for psoriasis, and, 3, the relationship between psoriasis and other infections.

For the purpose of determining these questions, the study of a series of cases was undertaken. I was able to collect nine patients for the study, extending over a period of nine months. Each patient was examined for pyorrhœa alveolaris and the presence of the Endamœba buccalis; was treated, regardless of the mouth findings, with one half grain of emetine hydrochloride hypodermically daily for seven days and treatment was discontinued for seven days. Another seven days' treatment was followed by seven days' intermission, and a final seven day treatment; also a wash of the fluid extract of ipecac for the gums was given during the entire treatment. If the psoriasis still remained, a careful search was made for some other source of infection; this was treated as conditions indicated, and the results were noted.

PSORIASIS AND PYORRHEA.

Of the nine cases, well marked pyorrhœa alveolaris was found in three with the endameba present. In two cases the endameba was found, but no pyorrhea, i. e., pus was found only in microscopic quantity: and in four cases, the search for the endameba was negative.

TREATMENT WITH EMETINE HYDROCHLORIDE.

In five cases in which pyorrhea or endameba was present, all were free from endameba and pus at

the end of the first week of treatment and week of rest, except two; in these pus and endameba were still present. One of these was cleared at the end of the second course; the other still had pus at the conclusion of the treatment and refused further treatment, or to permit further observation. In the two cases in which the pyorrhea was cured and psoriasis completely disappeared, treatment was instituted in one on April 3, 1915, which was dismissed on June 8, 1915; in the other, treatment was instituted on October 23, 1915, and the patient was dismissed January 3, 1916. The remaining two cases presented only endameba and no pus; in these the psoriasis remained unchanged.

In four cases in which pyorrhea or endameba was not present, the results were absolutely negative; the psoriatic eruption was not affected by the treatment.

PSORIASIS AND OTHER INFECTIONS.

The cases remaining uncured, minus the one refusing further treatment, were carefully searched for infections. In two of these a careful and extensive study failed to reveal any infection or coexisting disease, therefore they were dismissed. Both had extensive psoriatic lesions. The results in the remaining four cases were as follows:

Case II. Male, aged twenty-six years, weight 143 pounds, single, laborer. History: Severe malarial infection in the summer and fall of 1907. Gonorrhea 1910, and again 1912. Chancre, followed by secondaries, at the time of last gonorrhea, "took pills about six months." In 1914, red spot appeared on back and had gradually grown worse. Examination: Well nourished and healthy in appearance. Thorax and abdomen negative. No evidence of disease, except enlargement of posterior cervical, epitrochlear, and inguinal lymph glands and a psoriatic eruption on the back. There was one large circinate area, with a pale red centre and bright red periphery, which had a diameter from above downward of five and a quarter inches and three and three quarter inches across, between the scapulæ. In addition, there were twenty or thirty small bright red areas, varying from the size of a dime to a dollar, scattered over back and shoulders. Urine negative, serum Wassermann +++. No endameba nor pyorrhea.

Treatment: Emetine hydrochloride, as described in outline, concluded on September 23, 1915. No effect upon psoriasis. Injections of one half grain of mercuric succinimide and gradually increasing doses of iodide of potassium instituted September 26, 1915, and continued until December 2, 1915. Salivation developed and the patient quit treatment. Effect upon psoriasis, negative.

Case III. Male, aged forty-one years, weight 155 pounds, married, traveling salesman. History: Typhoid fever 1891, grippe 1893. Denied venereal infection. Rectal abscess 1906. There was a soreness around anus, and frequently underclothes were stained by discharge. "Rheumatism" winter of 1907 and again 1908. In 1910, small red area appeared over sternum; this gradually grew, but at times appeared to be better. Small areas scattered over chest and abdomen, which came and went. Examination: Heart, slight mitral regurgitation, lungs and abdomen negative. Joints tender upon pressure. Large dark red patch of psoriasis over sternum; several smaller areas on chest, abdomen, thighs, and buttocks. Fistula in ano, with external opening about one and one half inch to the right of the anus, and internal opening just within the internal sphincter; there was a cavity of considerable size containing pus, fecal matter, and débris. Urine and blood negative. No pyorrhea nor endameba.

Treatment: After a failure to cure the psoriasis with emetine the patient left Hot Springs in July, 1915, but returned for treatment of the fistula September 10, 1915. Operated on September 12th and on October 15th; returned to his home cured of the fistula. There was a slight improvement in the psoriasis.

Effect on psoriasis: January 15, 1916, patient returned to Hot Springs on business. The fistula was entirely well and there was no evidence of psoriasis.

Case IV. Male, aged thirty-four years, weight 135 pounds, single, laborer. History: Scarlet fever 1898, pneumonia 1904. Several attacks of malaria. Denied syphilis; gonorrhea many times, last infection, September, 1914, lasting until December, 1914. Several small red spots appeared on trunk, arms, thighs, and scalp in April, 1915, and gradually grew worse.

Examination: Chest, abdomen, joints, and muscles negative. Prostate enlarged and tender, left seminal vesicle thickened, indurated, and tender. Thirty to forty bright red spots, varying from the size of a dime to that of a half dollar, scattered over trunk, arms, and thighs. Many dark red spots the size of a dime on the scalp, but no loss of hair. Urine contained pus cells, hyaline and granular casts, and albumin, Wassermann negative. Endamœba buccalis obtained from scrapings of the roots of the teeth; no pyorrhea. Seminal and prostatic fluid contained staphylococci, streptococci, and colon bacilli, but no gonococci.

Treatment: Emetine treatment concluded August 10, 1915, no endameba present, but the effect on the psoriasis was negative. Massage of vesicles and prostate and irrigations with potassium permanganate solution instituted. Autogenous vaccine of organisms cultivated from seminal and prostatic fluid; 1,000,000,000 to the c. c., administered in gradually increasing doses to the maximum of one c. c., at intervals of three to seven days, as conditions warranted. Treatment instituted August 20, and on December 31, 1915, patient was dismissed, free from pus, bacteria, and psoriasis.

Case V. Male, aged thirty-three years, weight 139 pounds, single, laborer. History: Several mild attacks of rheumatism, the last in 1912. Frequent colds, and each winter had had sore throat. Skin disease appeared, 1910. Worse in winter, and in summer nearly completely disappeared. Worse now than ever. Denied syphilis; three attacks of gonorrhea, the last about 1913.

Examination: Heart, lungs, abdomen, muscles, and joints negative. Both tonsils very large, red, and boggy, pus exuding from crypts; pillars of fauces reddened and pharynx chronically inflamed.

Areas of psoriasis over both forearms and arms, extending up to the shoulder. A few small lesions were scattered over the trunk. The size of the lesions varied from one eighth of an inch to one inch in diameter. Some had coalesced, forming a large circinate lesion over deltoid muscle of left side. Color was dark red, and at times there was slight itching. All laboratory examinations were negative.

Treatment: June 8, tonsillectomy. Throat and nose treated with antiseptics.

Effect on psoriasis: August 17th, patient was dismissed as cured, no psoriasis being evident.

RECAPITULATION.

Of the ten patients all were treated with emetine hydrochloride and three recoveries resulted; these three had pyorrhœa alveolaris with the Endamœba buccalis. One case of pyorrhea failed to respond to the three courses of emetine, and there was no improvement in his psoriasis; he refused further treatment and was dismissed. One patient had a seminal vesiculitis, and after eradicating the disease with autogenous vaccine and other appropriate measures, the psoriasis cleared up. Fistula in ano, discharging pus, was found in one case; after an operation the fistula healed, and a complete recovery from psoriasis resulted. The removal of the infected tonsils was followed by the disappearance of psoriasis in one case. Syphilis was the only infection found in one case, and iodides and mercury had no effect upon the psoriasis. Two patients were found to have psoriasis, but no other disease or infection, consequently they were dismissed without relief.

CONCLUSION.

The small number of cases available renders the study far from complete; it is certain, however, that emetine hydrochloride has no direct effect upon psoriasis. It is probable that the cures from emetine treatment were due to the killing of Endamœba buccalis and to the subsequent death of the accompanying organisms.

The cases of recovery from psoriasis, after the removal or cure of the other infections, strongly suggest that these infections caused the disease. Further, on account of the character of the infections, it is suggested that the organisms most likely causing psoriasis were the staphylococci and streptococci.

MEDICAL WOMEN,

In History and in Present Day Practice,

BY MARY SUTTON MACY, M. D.,
New York,
Neurologist, Demilt Dispensary.

(*Concluded from page 198.*)

In a recent book on English medical women, Miss A. H. Bennett, who, by the way, is not a medical woman, but a journalist, writes:

It was the first five ladies who made a fresh application[1] for admittance to Edinburgh University, which was received quite favorably by the Senatus and the University Court. Doubtless it was easier to admit these "blue stocking" ladies than to refuse them. . . . Besides, there was the safeguard of the General Council of the University, whose assent was necessary before arrangements could be made for their admittance. The meeting of the council took place a few days before the winter session, and some time after the examination by which alone the medical students could gain entrance to the university for that term. Another visit was therefore paid to the dean of the medical faculty, who, as a great concession, allowed the ladies to present themselves for matriculation on condition that the examination should be considered void if the council decided not to admit women to the university. . . . The motion of Professor Mason, seconded by Professor Hughes Bennett, that "women be allowed to matriculate and form separate classes," passed by a large majority. The university felt that by this vote it had shown great breadth of mind, and such generosity that now it might at least make the affair a paying one. Consequently, the ladies were left to make their own arrangements for the separate classes, and for each class a guarantee of a hundred guineas was demanded. This the women agreed to, and received their precious cards proclaiming in red letters that they were *Cives academiæ edinensis*. . . . And now trouble began. After the first examination it was found that Miss Pechey had taken such a high place in chemistry that it was possible and even probable that she might win one of the Hope scholarships. This, from the men's point of view, was quite unendurable. They had gone against their traditions and upbringing in admitting the ladies to the classes, and the ladies, instead of showing gratitude by remaining in the background, not only competed with their best men, but seemed quite likely to win. . . . The two examinations resulted in four fifths of the women being in the honors list, Miss Pechey proving herself the best student of chemistry in her year. . . . The professor (Crum Brown) announced that the man below Miss Pechey would receive the scholarship, as the women's class was not eligible. Instead of meekly accepting the decision, Miss Pechey appealed to the Senatus. It was all very annoying and disturbing, and quite contrary to the professor's idea of womanly behavior, but, to his relief, the Senatus upheld his decision. . . . The excitement spread, and all forces of society, including the daily papers, were engaged in the struggle for or against the ladies. . . . As one of the friendly professors pathetically remarked at the time, if they would only be content to keep in the background, work on unobtrusively, lay claim to *no* distinction, and avoid all rivalry with the students, so much jealousy and trouble would be prevented. In other words, if these exceptionally brilliant women were to gauge the capacity of the men students, and then carefully refrain from doing better than the most stupid, they might be treated with kindly condescension.

[1]Miss Jex-Blake in a previous application, had been refused on the ground of its "not being advisable for the university to make alterations in the interests of one lady."

Doctor Wollstein sums up the subsequent history: "After the first session the professors refused to teach the women and the male students mobbed them. An appeal to the courts and even the parliament resulted"—after the second year—"in defeat of the women, who were obliged to go to Switzerland for their degrees." In 1874 the idea of founding a medical school for women in London took shape, Dr. Jex-Blake being chiefly instrumental in the school's organization. All obstacles were finally overcome when the Royal Free Hospital opened its wards to the women and the University of London, and the Conjoint Irish Boards consented to grant examinations and degrees to women. In 1886 a separate school for women was successfully opened in Edinburgh, and Dr. Jex-Blake was the first woman appointed as lecturer in a British university, holding the extramural lectureship in midwifery at Edinburgh and later at St. Andrews.

It would take too much space and be rather boresome to enumerate all the historical steps by which women have impressed their fitness and ability to practise medicine upon the general public, the hospitals, and colleges until in 1908, fifty per cent. of all the medical schools of the United States were granting degrees to women and every English university (except Oxford and Cambridge), all the Scotch universities, the Royal University of Ireland and Trinity College, Dublin, and the University College at Cardiff were open as well. Doctor Wollstein summarized the situation in 1908 most ably: "A fairly complete list would read as follows: The admission to medical degrees having been accomplished, first, in the United States in 1859, Switzerland followed in 1864, France in 1867, Sweden in 1870, Holland in 1873, England in 1877, Denmark in 1875, Italy in 1876, St. Petersburg in 1878, Finland in 1879, Scotland in 1886, Belgium in 1890, then Portugal, Bulgaria, Roumania, Greece and Mexico, then Austria in 1897, and finally Germany in 1900."

It is from lack of adequate hospital opportunities and staff appointments that women suffer most at present, though the outlook in the country at large is better today than it was even eight years ago. In the east these opportunities are still unjustly limited, as are also the appointments to teaching positions in the medical faculties. This discrimination can hardly be laid at the doors of the incompetency of the medical women with any degree of justice, and it is to be hoped that an adjustment may soon be reached whereby the women are appointed to faculty

and to hospital staff in a fairly just proportion to their relative numbers in the profession.

According to the twelfth census of 1910 the number of males in the United States who were gainfully employed was 22,489,425; of females gainfully employed, there were 4,833,630. Of these, 124,615 males and 7,387 females were returned as physicians and surgeons; in other words, there was about one medical man to every 179 men in other occupations and about one medical woman to every 653 women in other employments, whereas the proportion of women to men in the medical profession was about one to sixteen and of women to men gainfully employed about one to five, and the proportion of women to men in the population was about one to one, there being 24,851,013 males and 23,485,559 females in the census area of the United States who were sixteen years of age or older. To put these figures in another form: Of the males old enough to work, 90.5 per cent. were breadwinners; of the females, 20.6 per cent. Of the male breadwinners about 0.6 per cent. were physicians and surgeons; of the female breadwinners about 0.2 per cent. were physicians and surgeons; and of the whole number of the medical profession, 5.6 per cent. were women.

The history of medicine, having never been without the names of women practitioners for any appreciable time, goes far to prove that their medical work and medical writings were of average merit to say the least. That women are particularly adapted to the detail work required by laboratory research will be readily admitted and is amply demonstrated by the success in this field not only of a large number of nonmedical women, trained in other sciences or in specific lines of laboratory work, but also by the contributions of such medical women of the present generation as Frau Lydia Rabinovitch-Kempner, Frau Vogt, and Dr. Rachel Hirsch, of Berlin; Madame Curie, Madame Klumpke-Déjérine, and Madame Metchnikoff, of Paris; Dr. Lilian Welsh and Dr. Florence R. Sabin, of Baltimore, Md.; Dr. Janet Lane-Claypon, Dr. Ida S. MacLean, and Dr. A. Louise McIlray, of London, England; Dr. Marie Kjöiseth, of Christiania, Norway; of Dr. Lilian South (lately vice-president of the American Medical Association), of Bowling Green, Ky.; of Dr. Harriet F. Holmes, Dr. Lydia M. De Witt, and Dr. Gladys R. Henry, of Chicago, Ill.; of Dr. Martha Wollstein, Dr. Phebe L. DuBois, Dr. Louise Pearce, Dr. Anna I. von Sholly, Dr. Eleanor E. N. Van Alstyne, Dr. Bertha Van H. Anthony, Dr. Jacolyn Van Vliet Manning, and Dr. Anna W. Williams, all of New York, Dr. Adelaide W. Peckham, of Philadelphia, Pa., and others too numerous to mention.

In social service—which a Boston confrère considers the field *par excellence* for women—we find such well known women as Dr. S. Josephine Baker, director Child Hygiene Department of the New York city board of health; Dr. Frances Bradley, formerly of Atlanta, Ga., now in Government service in the Children's Bureau, Washington, D. C.; Dr. Janet Lane-Claypon, of London, England; Dr. Helen Y. Campbell, of Glasgow, Scotland; Dr. Lenna L. Meanes, of Des Moines, Iowa; Dr. Helen C. Putnam, of Providence, R. I., and Dr. Evangeline Young, of Boston, Mass., are all well known for work in infant welfare; Dr. Alice Hamilton, of Chicago, had made researches in occupational disease and with flies and typhoid, that were epoch making, and Dr. Caroline Hedger's (also of Chicago) work in the stockyards was a wonderful contribution to preventive medicine. Other women are entitled to credit in this field of service, especially the host of them who have ably cooperated in the campaign of public health education inaugurated in 1909 by the American Medical Association, but to enumerate them would need a volume, and this gratuitous philanthropic work was done by them as an incident to their scientific medical work and not as a specific field of service.

A brief and very incomplete list of the women entitled to be called well known in their specialties is herewith appended:

Internists.—The late Mary Putnam Jacobi, Elizabeth Cushier, Helen Baldwin, Sara J. McNutt, Emily C. Charles, of New York city; Eliza M. Mosher, of Brooklyn, N. Y.; Marion Craig Potter, of Rochester, N. Y.; Julia G. McNutt, of Albany, N. Y.; Sara M. Edwards, of Newark, N. J.; Ella Prentice Upham, of Asbury Park, N. J.; Evangeline W. Young, of Boston, Mass.; Kate Campbell Mead, of Middletown, Conn.; Mary B. Jewett, formerly of New York city, now of Florida; Mary Taylor Bissell, of New York; A. Louise McIlray, of London, England; Frances Culbert Van Gasken, of Philadelphia, Pa.; Sara A. Bond, of Boston; Josephine Beede, of Boston; Mary Hobart, of Boston; Emma Call, of Boston; Blanche A. Denig, of Boston; Hu King Eng, Mary Stone, of China.

Gynecology and obstetrics.—Anna E. Broomall, Ella B. Everitt, of Philadelphia, Pa.; Alice Weld Tallant, of Philadelphia, Pa.; Mary Gage Day, of Kingston, N. Y.; Elizabeth Jarrett, of New York city; Sara J. McNutt, of New York city; Rosalie Slaughter Morton, of New York city; Anna M. Galbraith, of New York city; Grace Peckham Murray, of New York city; Clelia Duel Mosher, of San Francisco, Cal.; Florence N. Ward, of San Francisco, Cal.; Bertha Van Hoosen, of Chicago, Ill.; Miss Janet Campbell, of Liverpool, England; Dr. A. Louise McIlray, of London, England; Dr. Annie McCall, of London, England; Mrs. Ethel Vaughan-Sawyer, of London, England; M. Marie Knudson, of Boston, Mass.; Marian Nute, of Boston, Mass.; Hannah G. Myrick, of Boston, Mass.; Rosetta Sherwood Hall, of Korea.

Pediatrics.—The late Dr. Mary Putnam Jacobi, of New York city; Sara Welt-Kakels, of New York city; Annie S. Daniel, of New York city; Mary Fulton, of China; Emelyn S. Coolidge, of New York city; Lenna L. Meanes, of Des Moines, Iowa; Millicent M. A. Cosgrave, of San Francisco, Cal.; Alice E. Sanderson, of London, England; Eleanor C. Jones, of Philadelphia, Pa.; Louise Taylor Jones, of Washington, D. C.; Annie Lee Hamilton, of Boston, Mass.; Beth Vincent, of Boston, Mass.

Surgery.—Adelaide Brown, of San Francisco, Cal.; Emily Dunning Barringer, of New York city; Rosalie Slaughter Morton, of New York city; Alice Gregory, of New York city; Elizabeth Hamilton Muncie, of New York city (Brooklyn); Late Rose Talbott Bullard, of Los Angeles, Cal. (died Dec. 22, 1915); Bertha Van Hoosen, of Chicago, Ill.; Martha Welpton, of Des Moines, Iowa; Miss Janet Campbell, of Liverpool, England; Mary de Garis, of Melbourne, Australia; Louise Garrett Anderson, of London, England; Florence Stoney, of London, England; Mrs. Mary A. Scharlieb, of London, England; Miss Aldrich Blake, of London, England; Caroline M. Purnell, of Philadelphia; Mary A. Smith, of Boston; Elizabeth T. Gray, of Boston; Augusta Williams, of Boston; Jane Kelly Sabine, of Boston; Emma B. Culbertson, of Boston; Sarah E. Palmer, of Boston; Florence Duckering, of Boston; Mary W. Klumpke-Déjérine, of Paris, France.

Orthopedic surgery.—Frau Grete Schuler-Helbing, of Berlin, Germany; Matilda K. Wallin, of New York city; Mary Hess Brown, of New York city.

Anesthesia.—Bertha Van Hoosen, of Chicago, Ill.; Mary Dickinson Berry, of London, England.

Electrotherapy.—Mary Arnold Snow, of New York city; Margaret Cleaves, of New York city; Gladys L. Carr, of Boston, Mass.

Specialists in diseases of eye, ear, nose, and throat.—Elizabeth, Queen of the Belgians; Late Emma E. Musson, of Philadelphia, Pa. (died Dec. 28, 1913); Mary P. Eddy, of Sidon, Syria; L. Rosa H. Gantt, of Spartanburg, S. C.; Helen Cooley Palmer, of Los Angeles, Cal.; Maud Carvill, of Boston, Mass.; Margaret Noyes, of Boston; Louisa P. Tingley, of Boston; Isabella D. Kerr, of Boston; Alice E. Wakefield, of New York city; Laura E. Hunt, of Philadelphia, Pa.

Dermatology.—Daisy M. Orleman-Robinson, of New York city.

Gastroenteric diseases.—Mary Dunning Rose, of New York city.

Cardiac diseases.—Maude E. Abbott, of Montreal, Canada.

Tuberculosis.—Mary P. Eddy, of Sidon, Syria; Mary E. Lapham, of Highlands, N. C.; Evelyn Fisher Frisbee, of Albuquerque, N. M.; Lydia Rabinowitsch, of Berlin, Germany.

This would hardly suggest that the sphere of woman's work in medicine is limited today; these medical practitioners are all recognized by the profession locally, many of them are known in all parts of the country, some even internationally, all have made and published original contributions to the medical literature of the day, much of this original work being of intrinsic and permanent value, so far as anything in medical science is really permanent. Practically no mention has been made of the host of medical women missionaries, whose stupendous medical work and well earned fame deserve an article devoted entirely to its consideration; it could not be at all adequately handled here.

Thus we may summarize the answer to "What have women accomplished in medicine since they began its practice?" by the statements: 1. They have made a large proportion of permanent contributions to medical science, especially if we take into consideration the fact that historically they have always been in a minority in the profession; and, 2, repeatedly crowded back and even out of the profession by the aggressiveness and numbers of their medical brethren, they have as repeatedly—and let us hope at last permanently—proved their ability to compete on equal terms with a fair degree of success and at least an average proportion of scientific achievement of the first rank. They have done this in spite of a most obstinate spirit of opposition on the part of their medical brethren; in spite of the seemingly insurmountable obstacles placed in their path by dogged masculine determination. Their courage has been dauntless, each attack more determined than those preceding, and actuated by the keenest sense of justice and of fair play.

SOME ORTHOPEDIC PRINCIPLES IN PEDIATRIC PRACTICE.*

By SAMUEL W. BOORSTEIN, M. D.,
New York,
Instructor in Orthopedic Surgery, Fordham University Medical School; Adjunct Visiting Orthopedic Surgeon, Montefiore Home and Hospital; Etc.

Orthopedics and pediatrics are to a certain degree interrelated. The word, orthopedic, comes from two Greek words meaning "straight" and "child" and the compound word means "to make the child straight." Thus the derivation of this term resembles that of pediatrics. In the early days of orthopedics, the pioneers really set themselves only to correct deformities of children. Though lately the work has spread to include the larger field of bone and joint diseases met in adults, still a great deal of practice is among children. It will, therefore, be interesting to those who have a great deal of pediatric practice, to get a short résumé of the cases we meet among the children and what in general is to be done for them.

Before giving details, I will emphasize a few points:

The orthopedist unfortunately often hears that the family physician has given assurance that the child would outgrow its bow legs; that the early pains of tuberculous bone and joint disease were "growing pains"; that the nontuberculous processes were "rheumatism"; that functional scoliosis was a matter of no importance. It is also an almost daily experience with the orthopedist to see a child brought in on account of a limp in one leg of a greater or less duration, and to hear the parents state that the trouble was all in the knee and due to a slight trauma, which was verified by their attending physician. With the child stripped, an observation of the gait, will, as a rule, at once disclose that the trouble is not in the knee.

This proves the necessity of examining the child, completely undressed, while it is lying down and while walking. Even with moderate observation, these erroneous diagnoses will be avoided. We must also keep in mind Wolf's law, that all prolonged alteration of the function of any part of the body, either congenital or acquired, is surely followed by anatomical changes. Thus, in addition to the original deformity, the ensuing changes in bones, muscles, and other structures make the restoration of function more difficult. Therefore, to obtain the best results, any deformity in a child should be attended to as early as possible.

The pediatric cases that are brought to the orthopedist can be classified as congenital and acquired. I will take up first the acquired deformities, as these are more frequent and also less noticeable to the parents than the congenital ones. Thus

*Read before Bronx County Medical Society, June 21, 1916.

there is greater responsibility for the attending physician who sees them.

ACQUIRED DEFORMITIES.

1. *Tuberculosis of the bones and joints.* Constitutes the majority of acquired forms. The usual time of attack is during the years of active growth and the preferred sites are the spine and the ends of the long bones near important joints, such as the hip and knee, which usually become infected and distorted, and are often destroyed. The general belief is that bovine infection is an important source of disease in children (Fraser, 10). It is reasonable to suppose that the intestinal tract is the route of infection in these youngsters, and depends upon infected milk supply.

The relation of trauma to bone and joint tuberculosis is still disputed, but may assert that a moderate contusion rather than a serious injury is more apt to be followed by tuberculous arthritis:

Of the clinical features, one has to remember that as a rule, the onset is extremely insidious and it is usually monarticular. At first the symptoms are mild, and pain is absent or not marked. If in the spine, a certain stiffness of posture and awkwardness in movement may be noted early. If in the lower extremity, a lameness passing off and recurring. Stiffness and muscular wasting of the affected limb may be marked. Later on, there is marked local swelling and local or referred pain. It occurs characteristically as night cries. Later on, abscess and sinus formation with amyloid visceral changes are present. Temperature is usually normal. In the joint cases, characteristic limitation of motion and deformity are striking features (Taylor, 24).

The diagnosis must depend entirely on the clinical findings and not wait for the radiographic verificacation as the plate is often negative in early cases.

In regard to treatment, the general system must be watched in the same way as pulmonary tuberculosis. Lately sunlight therapy under the leadership of Rollier has been instituted at Leysin (17) and it is considered that this marks the greatest advance in the treatment for many years. Of the local treatments, there is nothing better than immobilization and fixation. It makes no difference whether this is done by recumbency, plaster of Paris fixation, splints, braces, or one of the spinal operations. Anklylosis should be the main aim, watching at the same time to prevent deformities.

2. *Infantile paralysis.* The second infantile affection which requires the aid of the orthopedist is anterior poliomyelitis. Since 1907, when we had the severe epidemic in New York, scientific knowledge of the nature of the organism, the pathology, symptomatology, and prognosis have made great strides. I am sure that all have kept up with this progress, so there is no need of going into detail. I will mention only the orthopedic treatment:

In the acute stage, when the patient is generally paralyzed in one or more limbs, tender to touch and on motion, the best treatment is rest, keeping the limbs in proper position to prevent contractions, especially of the tendo Achillis which may occur to a troublesome extent in the first two or three weeks. It seems rational not to attempt to stimulate the seriously disordered nerve centres by massage, passive motion, or electricity. Electricity will never kill the organism as claimed by pseudo-scientists. No massage should be given until after sensitiveness has disappeared.

In the convalescent phase, after tenderness has gone, the sooner the patient is put on his feet and resumes activity, the better it is. It is advisable to defer active treatments for four weeks after the onset, provided of course, that the tenderness has left by that time. Active treatments consist of massage, electricity, and muscle training. Massage will improve the local and general circulation, facilitate the flow of lymph, and retard muscular deterioration; it will not regenerate the nerves. The value of electricity has been greatly overestimated. The unintelligent use of electricity month after month to the exclusion of other measures, has been one of the handicaps which has stood in the way of the best progress in many cases.

Muscle training, by which we mean medical gymnastic work, is the most important of the three. In its obvious forms, muscle training consists in aiding the patient to perform a certain movement with the hope of stimulating an impulse from the brain to the muscles. Another and very useful form of muscle training consists in getting the patient on his feet at the earliest possible moment. If the patient cannot do it himself, braces should be used, even crutches may be allowed in the beginning. Of course if any fixed deformity exists, it must be removed before treatment of any sort can be satisfactorily applied. Two or three years after the attack, operative measures may have to be undertaken, but this is out of the scope of this paper. Such cases may be referred to the orthopedist.

There seems to be no time limit as to improvement. In urging exercises and muscle training, one has to guard carefully against fatigue and overuse. (Lovett, 14, 15, 16.)

3. *Rhachitic deformities.* Another class of a common acquired infantile affection is rickets. This disease is due to improper diet and not to any congenital deficiency. Among four hundred babies born consecutively at Fordham Hospital which, by the courtesy of Dr. J. Telfair, the attending obstetrician of the hospital, were submitted to my examination for evidences of congenital rickets, I found only six cases. This corroborates the findings of most observers. The pediatrists, with their improved methods of feeding, have greatly diminished its occurrence. We still find, however, knock knees, bow legs, anterior curves of the tibia, coxa vara, and curved spines.

These deformities are never outgrown as commonly supposed, although some compensatory deformity may occur which conceals the gross manifestation and thus removes some of the external curves.

The defects may easily be corrected. If the infant is seen early, correcting the posture and putting the curved spine at rest or the application of braces will do the work. If seen later, operative procedures in the form of subcutaneous osteotomy and osteoclasis offer good prospects. The bone is broken through and put in the corrected position in plaster (1, 5).

4. *Weak and flat feet* are quite common and are evidently due to insufficiency of the muscles supporting the arch of the foot. The affection is usually a part of general physical debility or lack of muscle tone. Many cases are due to rickets or unsuspected anterior poliomyelitis. Shoes, especially those compressing the fore part of the foot and having heels, likewise those with a stiff shank inside, are contributing factors, by weakening the feet of the growing children.

In the way of treatment, attention must be given to prophylaxis as well as to general hygiene, proper gait, and proper footwear. It is best to order for

children moccasins or sandals, and at other times shoes with broad toes and loose uppers. Proper foot exercises may be added. If these precautions are carried out, no stiff flat foot plate will have to be employed (4, 8, 27).

5. *Scoliosis.* The last class we shall consider is scoliosis. In school children, the occurrence of lateral curvature, round shoulders, and other faulty anteroposterior postures are common, especially functional or false scoliosis. Among the causes, we find that poor hygiene, improper clothing, unsuitable school seats and desks (9, 21), and the carrying of heavy bundles of books under the arm play an important part. Empyema is a frequent contributor to incurable scoliosis. Some spinal deformities may be due to an inequality of the limbs.

Preventive treatment is important. Children should have proper clothing which does not pull from the shoulders. Proper exercises and adjustable chairs and desks at school are essential. Deformity of the lower limbs should be rectified. Failure to order exercises for the lungs after empyema is unpardonable.

The treatment of organic or structural scoliosis, which has been stimulated greatly by Abbot's work, has disappointed us. But if these cases come early under observation, a great deal can be done to improve them. Every child that carries one shoulder higher than the other probably has some kind of a lateral curve. The same is true of those who have a so called high hip, and these should be attended to early.

CONGENITAL DEFORMITIES.

1. *Congenital dislocation of the hip* has been carefully observed by the profession on account of Lorenz's visit to this country. Physicians are fortunately alert to that deformity. As the limb is noticed by the parents as soon as the child begins to walk, the patient is immediately brought to the family physician, who has, therefore, a chance to advise early treatment. Lorenz's bloodless operation is usually preformed. Sometimes several attempts have to be made before the head of the femur is retained. If unsuccessful, an open operation may be resorted to. After reduction, the head should be held in place for several months or a year, best by plaster of Paris fixation. If anteversion of the neck exists, it may be necessary to do an osteotomy.

2. *Club foot.* Another congenital deformity which attracts the attention of the physician quite early is club foot, usually as soon as delivery is completed. Occasionally he postpones treatment till the child begins to walk—which is a serious mistake:

> The deformity is a congenital displacement of the bones of the foot, chiefly at the midtarsal articulation with adapted alteration in the soft tissues, ligaments, tendons, and in the shape of the cartilage and bone in the joint surfaces of the astragulus and os calcis.
>
> The treatments should be started early within the first weeks of life. It is a source of the greatest gratification that it is now possible in almost every case of congenital club foot in which treatment is instituted at birth, to completely overcorrect the deformity in the first months of life. (Silver, 23.)

Treatment, in brief, consists in the gradual or forcible correction of the misplaced bones, with retention in an overcorrected position for a sufficient length of time for the cartilage, ligaments, and muscles to adapt themselves to the normal positions so that the correction becomes permanent. We use plaster of Paris fixation splints, which have to be changed frequently. We must remember that in infants it is hard to hold the foot in plaster. It is therefore necessary to include at the same time the flexed knee in a right angled position (20). Club foot is often combined with spina bifida, hence every child should be examined for the presence of a tuft of hair or a cleft in the spinous processes (7).

3. *Congenital spastic paralysis.* A stumbling block to the orthopedist and neurological surgeon is congenital cerebral spastic paralysis (hemiplegia, paraplegia, and diplegia) and spastic spinal paralysis (Little's disease). Still, the chances of improvement are better now than a few years ago. We may use appliances making locomotion possible and correcting a tendency to relapse. Tenotomies or myotomies should be done freely.

There are some new operations, such as Stoffel's, Foerster's, and Sharpe's. They seem to be promising, but are still in the experimental stage.

4. *Erb's palsy.* Of the numerous other congenital diseases we must mention Erb's palsy. Though Thomas (25), of Philadelphia, has written a great deal about the theory that this is caused by subluxation of the shoulder and tearing of the capsule, still the consensus is with Clarke, Taylor, and Prout (6), that it is due to injury to the fibres of the brachial flexus. It is usually the result of difficult labor and by forcible separation of the head and shoulder on the affected side. In treating we have to determine whether there is a fracture or not, then operate to unite the injured plexus.

5. *Torticollis.* We must not forget to mention torticollis or wry neck, which is quite common and must be attended to early. Cutting of the sternocleidomastoid is usually indicated. The results are good.

There are many other interesting conditions met in pediatric practice which are seen and treated by the orthopedist beside those I have described. I have merely endeavored to give a brief summary of facts. I hope that my readers have been able to gather a hint here and there from this paper which will be of use in the future. One thing I should like to impress upon them before closing, and that is the necessity of early diagnosis and the patient, long continued treatment necessary for these unfortunate cripples.

BIBLIOGRAPHY.

In the preparation of this paper the writer has made free use of some of the following articles and he wishes to acknowledge his indebtedness to the authors. This short bibliography may be of use to those who are anxious to go over more carefully some particular topic of the paper.

SOME EYE SYMPTOMS OF DIAGNOSTIC VALUE.*

By John J. Decker, M. D.,
New York.

I have not attempted in this paper to consider all of the diseases in which the eyes may be affected functionally or by organic change, but only those in which such affections occur rather regularly and in which, when they do occur, the eye symptoms become one of the prime diagnostic features of the disease. It is of no value to know, from a diagnostic standpoint, that a paralysis of one of the motor nerves of the eye may develop in typhoid fever. Its occurrence would create only a mild interest. But such a symptom arising in a man in apparent health would be of the deepest significance and would indicate a serious lesion of the central nervous system. I have, therefore, tried to confine myself to those diseases in which eye symptoms, when they occur, are an aid in diagnosis. I have arranged my symptoms roughly, but not strictly, on an anatomical basis, taking first the exterior of the eye and proceeding to the deeper portions as they present themselves.

In this arrangement exophthalmic goitre is the first disease to be considered. In its typical form it presents an eye symptom which is *sine qua non*. But not all cases are typical and the exophthalmos is not essential. When present it may be bilateral or unilateral; ordinarily the former. In addition to this classical symptom, there are other symptoms exhibited by the eye and they may be present when exophthalmos is absent. These are the Graefe sign, the Dalrymple sign, and the Stellwag sign. The Graefe sign consists in absence of the downward movement of the upper lids when the eyeballs are turned downward. The Dalrymple sign refers to the staring expression presented by patients with this type of goitre and is due to the widening of the palpebral fissure. The Stellwag sign is the infrequent winking of these patients. In these cases it is said the eyes may remain a minute or more without winking. Normally winking occurs from two to five times a minute. These signs are not pathognomonic, but are said to exist at some time throughout the course of the disease in most cases, and may be of diagnostic aid.

Thrombosis of the cavernous sinus is a cause of exophthalmos; marked edema of the lids is an accompanying symptom. The infection of the sinus may occur by extension from the lateral sinus and is here of otitic origin. It may originate in an infected nasal accessory cavity. Cellulitis and furuncle of the face are common sources of the infection; the tonsils and teeth are occasionally at fault.

When considering the eye as a source of diagnosis, syphilis in one or another of its manifestations looms up large. This protean disease is disclosed by both external observation and fundus examination. A complaint of double vision in an adult when turning the eyes to the right or to the left or up or down, is a sufficient reason for taking a blood specimen for the Wassermann test. The paralysis of exterior muscles thus indicated may be marked enough to be easily seen if the eye is moved to a sufficient degree in the direction of the action of the affected muscle or muscles. The seat of the lesion in the syphilitic paralyses varies. It may be in the orbit, being a direct involvement of the muscle or nerve by gummata or by orbital periostitis; there may be gummata and meningitis at the base; gummata or degenerations in the nuclei. A nuclear lesion is the commonest cause. The third nerve is the nerve most commonly attacked and it may be involved in one or all of its branches. The paralysis is usually progressive without treatment, though it may be transient, resembling in this the tabetic paralysis.

Syphilis, however, is not the only cause of exterior ocular paralyses. Other diseases to be mentioned are diphtheria, cerebrospinal meningitis, and tuberculous meningitis. Cerebrospinal meningitis frequently causes an abducens paralysis. The paralyses of diphtheria are interesting inasmuch as they appear during convalescence and are, therefore, of importance in calling attention to a preceding infection, the true nature of which was perhaps unsuspected. In fact, a paralysis of any of the muscles of the eye in a child who otherwise appears well, will usually be due to a preceding diphtheria. An involvement of the ciliary muscles is the one most frequently present and is disclosed by a complaint of hazy vision. Postdiphtheritic paralyses of ocular muscles almost invariably disappear completely. Cerebral hemorrhage and other causes of pressure in the brain, such as tumor and abscess, are to be kept in mind as sometimes causing ocular paralysis. Disease of the nasal accessory sinuses also rarely exhibits this symptom and the presence of a paralysis may lead to the discovery of the condition.

With a *transient* paralysis of any of the extrinsic eye muscles, tabes would be first thought of. If it is combined with irregularly shaped pupils (another early sign), the diagnosis of an oncoming tabes would be quite safe in most cases. Another pretabetic symptom sometimes present is inequality of the pupils. This symptom does not occur so frequently in tabes, however, as in paresis, in which disease it is of prime importance. An irregular

*Read before the Medical Society of the Borough of the Bronx, January 17, 1916.

pupil is present in a large majority of the cases; exterior ocular paralysis in about one third. Any of the muscles may be involved in tabes, the external rectus most frequently, with one or more muscles of the third nerve group a close second. Ptosis is commonly seen. Rarely there is a paralysis of all the exterior muscles of the eye or ophthalmoplegia externa.

The Argyll Robertson pupil is the most important eye symptom in this disease, since a pupil of this character combined with loss of knee jerk, with or without optic atrophy, establishes a diagnosis. In no other disease is it found so frequently or present over so long a period of time. It vies with irregular pupils for first place as the *earliest* symptom. It is almost invariably bilateral and is frequently associated with miosis, though it may coexist with any size of pupil. It occurs in seventy to eighty per cent. of all tabetics. It is present in some other diseases of the central nervous system, in paresis particularly, though not so regularly and only for a short period.

Another symptom which is suggestive of tabes even when it is the only symptom present, is optic atrophy. It makes its appearance early and is bilateral and progressive, often leading to complete blindness. This symptom has been noted fifteen or twenty years before other tabetic signs were evident. It is said that twenty-five per cent. of tabetics acquire this change in the optic nerve.

To continue with the consideration of the exterior muscles, it is to be recalled that multiple sclerosis also presents paralysis as a frequent symptom, about twenty per cent. of all cases, according to Hirsch, having this symptom. Here again the paralysis is transitory, being marked by frequent exacerbations and intermissions. The abducens is the nerve most frequently involved. There may be an involvement of the associated movements of the eyes to the right or to the left, the externus of one eye and the internus of its fellow being attacked.

Nystagmus, when present, is the most important differential eye symptom in this disease. It may be a true nystagmus or a pseudonystagmus. There is only one other disease of the central nervous system in which it occurs with any frequency, and that is syringomyelia, in which it is the only eye symptom worthy of mention. Optic atrophy occurs in a certain number of those afflicted with multiple sclerosis, but in this disease it does not develop to the extreme degree found in tabes. It may involve only a portion of the disc and in some cases even an improvement in this symptom has been noted. The pupillary reflexes remain normal in most cases, which is a fact of significance in the diagnosis. Tremor, scanning speech, and nystagmus are the characteristic symptoms of this disease.

Paresis. In this disease the extrinsic eye muscles are rarely involved to a marked degree. This may be a valuable differential sign between paresis and tabes and syphilis. In paresis the paralysis is slight when present at all, and sometimes is noted only by diplopia. The pupillary signs are the most important of the eye symptoms, and are of the greatest value in determining the presence of paresis. Inequality of the pupils is among the earliest signs, and may be present before any other typical physical sign is noted. Irregularity sometimes accompanies the inequality. Miosis is present in about one third of the cases. The Argyll Robertson pupil is present during a part of the time in a fair percentage of pareties, but is not of long duration, differing in this from the same sign in tabes in which it exists throughout the greater part of the course of the disease. The loss of accommodation is an early sign. Optic atrophy often falling short of a total involvement of the nerve may develop at an early stage.

Myasthenia gravis. In this disease ptosis is a marked symptom and may be the first noted. It is usually bilateral and occurs in almost all cases. There may be an ophthalmoplegia externa. Double ptosis, double facial paralysis with paresis of the muscles of mastication, dyspnea, and general bodily weakness is the characteristic group of symptoms.

Before leaving the exterior of the eye attention should be called to inflammations of the cornea (keratitis), which may be the means of revealing the existence of an inherited syphilis. They may also be due to an acquired infection. Certain opacities of the cornea are also a suspicious sign. Phlyctenulæ of the cornea and conjunctiva are scrofulous indications and should lead to an investigation of the general condition of the patient, who may react to tuberculin.

The iris is the subject of inflammations from various causes, syphilis being in the lead. A plastic iritis may therefore be a valuable indicative sign. Old iritic adhesions are likewise to be laid under suspicion. Other syphilitic manifestations in the iris are papillary iritis occurring in the secondary stage, in which small nodules are observed at the pupillary margin, usually in both eyes, and gummatous iritis in which a single nodular mass is found in the ciliary zone.

Then there is the form known as rheumatic iritis. The term, rheumatic, is in a state of metamorphosis. Formerly a rheumatic attack was a visitation of God. It came from an unknown source. Hence many acute lesions of unknown origin were called rheumatic. Today we believe rheumatism to be an infection and we search for the focus. Probably with diligent search most cases of iritis would be traced to some focus of infection existing elsewhere in the body. Hence the teeth, tonsils, and other known haunts of infective material should be investigated when we are confronted with an iritis in which the local conditions give no clue to the origin of the inflammation. The eradication of such a nidus of infection may add immeasurably to the general sense of well being of the patient, beside removing a source of real danger, and his attack of iritis will not have been in vain.

A gonorrheal urethritis is one of these sources of infection and, according to Weeks, many of the cases of attacks of so called rheumatic arthritis which precede an attack of iritis, if closely investigated would be proved to be gonorrheal in origin. Likewise some cases of iritis without the history of an arthritic attack may exhibit a urethritis. This form of iritis is therefore of interest in that it may lead to the discovery and proper treatment of a

source of infection which had been neglected or improperly treated. Tuberculosis of the iris is not very common, but its presence either in the miliary form or as a solitary tubercle may be the means of calling attention to a pulmonary tuberculosis, since it is necessarily secondary to some focus without the eye. It occurs only in children and young adults. Syphilitic and tuberculous lesions of the ciliary body are similar to those of the iris.

A condition in which the iris, ciliary body, and choroid each have a part is uveitis. This is a low form of inflammation, most common in young adult life. It is characterized by the formation of minute opacities in the vitreous and aqueous. These opacities are most easily seen as they lie against the posterior surface of the cornea, where they form easily recognized deposits. A tuberculous origin for this condition is to be sought for, as this is perhaps the commonest cause. Syphilis, gonorrhea, and other infective agents are not to be overlooked.

A portion of the eye of great interest to us is the retinal layer. Lesions of this membrane furnish information of the greatest value to the physician and to the patient. A retinitis presenting hemorrhages and exudates is one of the most interesting of the lesions. This may be due to nephritis, diabetes, or arteriosclerosis. Tuberculous retinitis in the young is also a source. Albuminuric retinitis is said to display characteristic features, but the other diseases mentioned may simulate this form very closely. However, the point of interest and value is that the discovery of this lesion has led to an examination of the urine with the disclosure, possibly, of grave conditions.

The nephritis found with a retinitis is usually of the interstitial variety, and the patient rarely lives more than a few years after the discovery of the retinal lesion. This unfavorable prognosis does not apply to the retinitis occurring in the albuminuria of pregnancy. In connection with nephritis should be mentioned sudden blindness which becomes complete in a few hours. This may come on without any lesion of the fundus, and is due to uremic intoxication of the optic nerve and retina, or of the cerebral cortex, or of both. The pupillary reactions are normal in such an attack, and there may be no other signs of uremia. If the patient survives the uremic attack the amaurosis disappears completely. Diabetes and nephritis may coexist in the one case with a common retinitis.

Embolus of a retinal artery (sudden blindness) may be due to an endocarditis, and such an accident will direct attention to the heart. Of course, other sources of emboli may operate here. The retinal vessels may be the source of valuable information, even when hemorrhage is not present. I refer to evidences of sclerosis of these vessels. The retinal vessels are the only portions of the vascular system open to direct and fairly intimate inspection. When we add to this that they are very tiny in calibre, the largest being only a fraction of a mm. in size and the smallest about 0.01 mm., the possibility of discovering general vascular wall changes at a very early stage of the process is easily seen. Sclerosis of these vessels presents a definite picture, easily diagnosed. Vascular changes are of vital importance to every one past middle life, and an early detection of this condition is of the utmost value.

Dr. Edward Jackson, of Denver, has expressed this so aptly, that his words will bear repeating: "A great many of those who suffer from angiosclerosis go to some one for advice with reference to wearing glasses. If every one of them could be submitted to a careful ophthalmoscopic examination by a competent ophthalmologist the intelligent regulation of the lives of those affected would constitute one of the great triumphs of preventive medicine. This disease comes at the time when age predisposes men to listen to wisdom and lengthen out their remaining years. Though the knowledge of the danger may often come too late, it would often be of great value. Everything we can do to make more general the early recognition of angiosclerosis will bring added lustre to the crown of medical science and added service to our fellow men." A condition of some interest involving the retina, and of importance as a confirmatory sign, is the cherry spot of amaurotic family idiocy. It is situated at the macula and is invariably present in this disease. It is always accompanied at a later stage by optic atrophy.

Neuroretinitis is a common syphilitic manifestation, as are choroiditis and chorioretinitis. Choroiditis should always be suspected of being syphilitic until some other cause is proved. This is the commonest cause, and both the acquired and the hereditary form may be followed by it.

A congenital choroiditis is a sign of the latter form. The discovery of a tuberculous choroiditis (in which the tubercles are seen scattered throughout the choroid) may rarely be of help in clearing up the diagnosis in an obscure case of miliary tuberculosis. It sometimes accompanies tuberculous meningitis, and when present, the choroiditis positively establishes the diagnosis.

The diagnostic importance of atrophy of the optic nerve in tabes, multiple sclerosis, and paresis has been mentioned. In neuritis of the optic nerve we must look for syphilis, a frequent cause. In the form of neuritis known as choked disc, we have an important symptom of brain tumor. This is not the only cause of this type of neuritis, as it may also be due to meningitis, to abscess of the brain, or to hydrocephalus. The symptom is due to pressure within the skull and may be of aid in differentiation in some cases.

In the foregoing I have attempted only to call attention to eye symptoms which, when they occur, are rather obvious. Incidentally the value of the ophthalmoscope is implied. This implement should be equally prized with the sphygmomanometer and the stethoscope.

1939 Washington Avenue.

Comparative Toxicity of Morphine and Morphine-narcotine (Narcophin).—David I. Macht (*American Journal of the Medical Sciences*, July, 1916) has studied the comparative toxicity of these drugs on various animals and finds that in general it is about equal, and concludes that it is not advisable to administer narcophin clinically in doses larger than those of morphine.

Our Readers' Monthly Prize Discussions

Twenty-Five Dollars Is Awarded for the Most Satisfactory Paper

All persons, whether subscribers or not, are invited to compete for the prize of $25 offered for the reply deemed best by the editors to the following questions:

CLXXII.—What are your methods of resuscitation and aftercare of persons apparently drowned? (Closed.)

CLXXIII.—How do you perform circumcision? (Answers due not later than August 15th.)

CLXXIV.—How do you treat ivy poisoning? (Answers due not later than September 15th.)

The award will be based solely on the value of the information contained in the answer. No importance will be attached to literary style. Answers should preferably contain not more than six hundred words, and should be written on one side of the paper only. All papers submitted become the property of the JOURNAL, and should bear the full name and address of the author for publication. The prize will not be awarded to the same person more than once within a year.

The prize of $25 for the best answer to Question CLXXI has been awarded to Dr. Lionel C. Charbonneau, of Brooklyn, New York, whose paper appears below.

PRIZE QUESTION NO. CLXXI.

THE TREATMENT OF SPRAINED ANKLE.

By LIONEL C. CHARBONNEAU, M. D.,
New York.

Our past masters, Gross, Paget, Erickson, Bryant, *et alii*, were unanimous in their treatment of sprains. They enjoined rest, the application of starch bandages, plaster of Paris casts, and, at times, strapping. Erickson epitomizes their views when he says: "In the vast majority of these injuries all that is necessary is to put the part at rest for two weeks. It may require months and even years to restore complete usefulness to a sprained joint. A sprain is often more severe than either a fracture or dislocation of the same joint."

Surgeons today exhort a little more; beside the usual rest and lotions, they advise gentle massage and early passive motion, which will restore the normal function of the joint, but requires considerable patience and time.

It has been my good fortune to treat a great many sprains among members of the theatrical profession, baseball players, and athletes in general. The deformity, after a severe accident, may occasion a doubt as to the existence of a fracture. A fluoroscopic examination or skiagraph is made to determine extent of injury. All sprains are treated alike.

A soft metal electrode is placed over the injured parts, held in position with a roller bandage, the positive side of the static machine is connected with a rheophore, usually a chain, to the metal electrode, the negative side is grounded, and the static wave current is given. A spark gap of from two to three inches at the beginning of treatment is readily tolerated by the patient. The gap is lengthened from two to twelve inches as tolerance increases; two or three interruptions to the second should not be exceeded. The static wave is given for twenty minutes, the electrode is removed, and the patient is connected with the negative side of the machine and the brush discharge is given as we sweep the electrode over the injured parts for fifteen minutes. The treatment is terminated by applying indirect sparks, avoiding bony prominences. In a recent sprain, the treatment is repeated within four or five hours, omitting the indirect sparks. In the majority of cases the patient returns on the following day practically well. After one or two more treatments the patient is discharged. If the sprain has existed twenty-four hours or longer, the treatment is repeated each day until cured, which seldom requires more than five days.

In so called "chronic sprains" or "irritable joints" the attendant must distinguish between rheumatism, gout, and syphilis. It happens, at times, that the physical agent, electricity, cannot be administered to sprains, owing either to idiosyncrasy, or refusal on the part of the patient, or because the doctor is not familiar with the agent. Where and when electricity cannot be used, submerge the sprained joint in hot water, employing gentle massage and passive motion for twenty minutes, dry the parts thoroughly, rub well into the skin an ointment of menthol, one dram to the ounce; the menthol relieves pain by reflex constriction of the peripheral arteries. A snugly fitting bandage terminates the treatment. The séance is to be repeated, night and morning. The normal function of the parts will not be fully restored for, perhaps, two weeks—a remarkable contrast compared with the immediate results obtained from the electrical method.

N. B. In recent sprains the second electrical treatment should be given within four or five hours after the first, if brilliant and "miraculous" results are desired. I have treated many severe sprains with great deformity to the parts. The macroscopical appearance would make me hesitate in giving a favorable prognosis, and on the following morning the patient would make his or her appearance at the office without support or cane, saying, "Doctor, I would have telephoned to inform you that I was well, but I knew you would not believe it; give me another treatment for good measure." Every physician can obtain similar results.

N'oubliez pas, celui qui veut, celui-là peut.

Dr. J. Otis Carrington, of Malden, Mass., writes:

Treatment should be directed to the relief of pain and swelling, restoration of the ankle to normal, and especial care directed to the prevention of weakness and ankylosis. When the sprain is first seen and is recent, the first effort should be to prevent further effusion of blood by the use of cold applica-

tions and pressure. The limb should be elevated and firmly bandaged and an ice bag applied, care being taken not to bandage too tightly on account of shrinkage when dry. When pain is great, a solution of lead water and laudanum applied to the joint is useful. The following liniment is also useful:

℞ Tincturæ aconiti, ... 10 grams;
Tincturæ opii, ... 30 grams;
Linimenti belladonnæ, ... 60 grams;
Linimenti chloroformis, ...q. s. ad. 180 grams.
M. Sig. For local use.

Heat, locally, is often efficacious for pain, when cold fails to relieve. We combat inflammation with the usual remedies, and when pain continues troublesome administer Dover's powder in ten grain doses.

Enforced rest, firm pressure, and support of the ankle by strapping with zinc oxide adhesive tape should be used. Great care should be exercised in strapping so that the support is firm and uniform and will not loosen. The adhesive tape should be one and one half inch wide and of two lengths, eighteen inches and twelve inches. Holding the foot in dorsal flexion and abduction, start with an eighteen inch strip well behind at the junction of the lower with the middle third of the leg on the uninjured side, and carry it down under the heel with considerable tension across the side and up on the other side of the joint. The middle of the twelve inch strap is applied to the heel, and the two ends are carried over the foot, but not far enough to meet. Leg strips and foot strips, i. e., long and short, should alternate, interlacing and overlapping about one third of the previous strip each time until the joint is covered. Strapping supports the ankle, prevents the effusion of blood, supplies the necessary pressure, and at the same time fixes the joint and supports the torn ligaments.

After two or three days, massage should be employed, followed later by passive motion. In the early stages massage should be very light, consisting of gentle stroking movements from above the ankle toward the trunk. They assist the absorption of extravasated blood and lymph, relieve pressure on sensory nerves, and diminish pain. Massage should last from twenty to thirty minutes. As the swelling subsides, we massage more firmly, including the joint. Passive motion should be very gentle at first, limited to a few movements at a time, and gradually increasing the number of movements and the time.

Massage and passive motion are important and should be gradually increased from once to three or four times a day. It is only by these means that weakness and ankylosis can be prevented. At this stage heat is a valuable synergist in loosening tightened ligaments and joints.

If the injury has been slight, we support the joint with strapping and allow the patient to use it cautiously. We do not allow a patient with a slightly sprained ankle to "walk it off." We keep it at rest until strapped; then sometimes, in slight sprains, exercise may do good by preventing stiffness. Each case is a law unto itself.

Dr. I. M. Leavy, of New York, remarks:

The usual and most satisfactory treatment for the ordinary ankle sprain is the adhesive plaster strapping, originated by Gibney, and applied as follows: Strips of zinc oxide adhesive plaster are used of one inch width, the first to be placed with its centre under the os calcis and the ends reaching about two or three inches above the malleoli on each side. The second, with its centre behind the heel, reaches forward to the tarsometatarsal joint without the ends meeting each other. The next strip covers one half the first and follows it in the same way; and another strip covers one half the second, in like manner, alternately forming a criss cross arrangement until the entire ankle and heel are encased in adhesive plaster, except for the narrow space on the dorsum of the foot. Special care should be taken that the adhesive is applied smoothly and that wrinkles are eliminated; points of greatest tenderness may be reinforced by additional strips. A gauze or muslin bandage may be applied over the strapping, to retain it in place and prevent the edges from becoming loose.

The modifications of this method are many, and some are very efficacious in that they are applicable to the character of the injury—as in the occurrence of sprains on the inner side of the ankle; in such a case adhesive plaster is best applied in the manner devised by Whitman.

Two or three strips of zinc oxide plaster, about two inches in width, are applied, beginning at the outer side of the leg, just below the knee joint, carried down over the external malleolus, with the foot inverted; at right angles to the leg, tension is put on the plaster and it is drawn under the os calcis up on the inner side of the leg to opposite the beginning. One or two narrow straps are applied around the leg circularly to hold the longitudinal one in place. Then one inch strips are used for reinforcement, starting about two or three inches in front of the external malleolus, continuing under the arch of the foot, to the tarsometatarsal joint, each covering one half of the preceding strip, until most of the arch and the heel are covered.

In cases of sprain to the outer side of the ankle the adhesive plaster may be applied in the same way, with the foot in eversion. With the adhesive dressings the patient is encouraged to walk if possible, as a natural means for increasing circulation and restoring function.

Usually two or three applications of adhesive will suffice. For the subsequent weakness of the foot after the period of immobilization, tonicity will be aided materially by alternate douching with hot and cold water and deep massage.

Dr. Jesse D. Friedman, of New Kensington, Pa., suggests:

During the first twenty-four hours apply cold to the ankle. Later, heat and massage, about twice a day, are begun. The cold is applied at first either in the form of cold compresses or as an ice bag, and the heat as hot compresses or a hot water bag or bottle.

The injured joint should at once be put at rest and the limb elevated. Rest of the joint is obtained by a firm bandage or by adhesive strapping. In my work I combine both—first strap and then apply the bandage over it. By fixing the joint in this

way, we obtain support for the joint and elastic compression, which in itself limits the excessive reaction. As the external lateral ligament is usually stretched or torn, the adhesive strapping is applied over this area. I use strips about half an inch wide and long enough to reach from the arch around the sole and over the outer border of the foot across the ankle joint. Each strip overlaps the previous one, and each succeeding strip is placed higher, so that finally the joint and the external malleolus are covered. Before applying the adhesive, it may be beneficial to paint the skin over the joint with equal parts of tincture of iodine and tincture of aconite. Where pain is great, local application of lotio plumbi et opii may be efficacious.

In young patients, difficult to keep at rest, a plaster cast may be employed, the method of application being the same as for the adhesive.

Later, as the reaction subsides, massage is employed. In doing this a liniment may be used, such as chloroform or camphor liniment. Massage should not be delayed too long nor employed too vigorously, but instituted about the second or third day, with the intention to promote healing and prevent stiffness.

Dr. Louis Neuwelt, of New York, believes:

A sprained ankle should be treated by firm bandaging before swelling ensues, to give the joint functional rest for the first two or three days, to limit the swelling, and to hasten the absorption of the effusion; later, when the pain has subsided, massage and passive motion may be given. For severe pain, morphine may be administered.

In a mild sprain, or if the patient is seen shortly after the injury, the ankle is immobilized at once in plaster of Paris for a few days, or strapped with zinc oxide adhesive plaster, applied, to avoid circular constriction, in the following way: The adhesive strips are cut one half inch wide and in two lengths, twelve and eighteen inches. Place a long strip in front of the big toe, carry the strip back around the heel, keeping just above the contour of the sole, and bring the strip back across the dorsum of the foot to the starting point. All the strips should be drawn across tightly. Then a short strip is placed above the ankle, carried under the heel, and up toward the opposite side. The long and short strips are placed alternately in this fashion, each overlapping the one preceding, until the foot is nearly covered. The whole foot is then covered with a roller bandage and kept at rest. No weight should be put on the injured foot, and the dressing should be left on until the pain and swelling have subsided. If the plaster becomes loosened, additional strips are superimposed.

Should the patient be seen some time after the injury, or after the swelling has set in, apply pressure with a wet dressing of aluminum acetate and an ice bag over it. After a day or two, if there is no relief, use hot fomentations, or place the foot in hot water for twenty minutes every three or four hours.

Massage is a most valuable means of aiding recovery in sprains, especially where there is disturbed circulation in the joint. After the swelling has disappeared, massage with the palmar surface of the hand may be given. If tenderness persists, the health tissues just above the ankle should be stroked gently in the direction of the blood and lymph currents (toward the heart), and the joint approached gradually. At first very little force is used, but the movements may be gradually increased in vigor, and toward the end active manipulation is used. Walking is now allowed, but only with a crutch. If massage causes a return of the swelling, discontinue it for a few days, to be tried again later.

Hot air bakings for one hour during the intervals of massage, and continued for several days, have given good results.

Dr. L. Hubert, of New York, observes:

In sprains of the ankle of mild degree measures to stimulate the local circulation are begun at once while the joint is used only moderately. As soon as possible after the injury the ankle joint is baked in a hot air oven, massaged for a few minutes, or massaged without baking. Either massage or baking or both alternately are then used daily for two periods of half an hour each. The massage periods are gradually separated by a longer interval and alternate douches of hot and cold water added. Vibratory massage is also of use.

The joint is supported by a bandage and moderate use is encouraged. We can also allow the patient to walk, the ankle efficiently supported by adhesive plaster strapping, applied as follows: Overlapping straps about twelve inches long and half an inch wide are applied to the foot with the sole inverted. The first strap starts at the outer border of the foot, near the little toe, passes horizontally along the back of the heel, ending on the inner side of the foot about its middle. The second strap is applied vertically and passes from the lower part of the calf of the leg down alongside the tendo Achillis, under the heel, and terminates above and behind the malleolus. The other straps are similarly applied, a little above and overlapping by about one half the first and second straps respectively until the whole ankle is covered. To suit any special indication the manner of strapping can be modified. In sprains of a severe type, where, because of the great effusion of blood we expect an extensive tearing of the ligaments, also in children, neurasthenics, and where arthritis deformans of any degree is present, it is best to keep the foot at rest in a plaster of Paris or wood splint for about two weeks. By this time the effusion has nearly subsided and then we begin massage, active and passive motion. If the massage is irritating it should be stopped. Hot air baking is useful and should be given daily for about half an hour. A hot douche, followed by a cold one, when the effusion has all subsided, is also effectual. Restricted but gradually increasing use should be allowed the joint after the effusion has disappeared, but unrestricted use is only permissible after the synovial membrane has become apparently normal and the use of the joint is not accompanied or followed by severe pain. I prefer this procedure to ice application and massage, which are commonly used from the start, in order to diminish or to get

rid of the bloody effusion. Stiffness and muscle atrophy are not to be feared with the short fixation, which is only long enough to quiet the inflammation in the joint, whereas without fixation the healing of the ligaments may be incomplete. The result is a stiffness of the ligamentous apparatus and an uncertainty of the foot, which led to frequent repetitions of the sprain, chronic sprain, and flat foot.

By proper treatment and after care a sprain of the ankle should heal without leaving any functional disturbances, but we frequently meet chronic sprains which we have to treat. At first we use complete rest and fixation of the joint, until the irritation of constant use has been partly recovered from. In slight cases restricted use is enough. A local hot air bath daily is of great value. As soon as the excessive irritation has subsided, massage not only of the ankle joint but of the whole limb is indicated. Alternating hot and cold douches, electricity, and liniments where massage is not available, are other measures of use .

We should not forget that in some cases of chronic sprain of the ankle associated with flat foot we have a shortened gastrocnemius as a complicating factor, and in such cases the muscle must be lengthened by stretching.

(*To be continued.*)

Contemporary Comment

Newspaper Notoriety.—We are quite willing to admit, remarks the *Journal of the Indiana State Medical Association* for June 15, 1916, that occasionally a doctor's name gets into the daily papers without his knowledge or consent, but when you repeatedly see some doctor's name mentioned in daily papers in connection with medical and surgical cases, it is a safe bet that the doctor permitted or even solicited the use of his name. When a doctor's name is connected with a technical write up of a case it is a certainty that he is responsible for the information and the privilege of using his name in connection with it. Newspaper reporters not infrequently say that news concerning an operation is legitimate news for publication, but we do not believe so, and no information of any kind whatsoever concerning an operation should come from the attending physician.

The Healthfulness of Crying for Infants.—A "good cry" is an expression often made use of, observes *Pediatrics* for June, 1916, and at first sight seems decidedly misapplied, but upon a little consideration it will be allowed that after all in many instances it is not an inappropriate term. Of course, crying is usually associated in one's mind with grief or pain, although even when such is the case crying is a relief and thus does good. There are many occasions, however, when crying, and violent crying, is of the most decided benefit to children. In reference to this the *Hospital* says: "In children a great change takes place during crying in the manner in which the respiration is carried on. Expirations are prolonged sometimes for as much as half a minute, and are interrupted by short inspirations. During expiration, the glottis is contracted so that intrapulmonary pressure rises considerably, and there can be little doubt that it is the equal distribution of this increased air pressure throughout the whole of the chest leading to dilatation of portions of the lung that have become more or less collapsed, that is the explanation of the great benefit which often results from crying, in cases of infantile bronchitis, and of the large discharge of bronchial mucus which so often follows. Children may become very blue during the paroxysm, but the deep respirations, which succeed quickly, restore the circulation to a better condition than before in consequence of the large lung space available. It might be added, in cases of empyema, too, when pus has collected, that if a child when being operated on cries, it is a great help toward getting rid of the purulent matter."

Prevention and Cure of Pellagra.—The Public Health Service is systematically popularizing the diet theory of pellagra prevention, and timely circulars have been issued dealing with the detail in diet to be followed at this season, when pellagra usually develops. The circular states the diet recommended by the health service will not produce results if followed for a few days only—it must be continuously and consistently used. A rigid, unvaried diet is undesirable, but the necessity of minimizing carbohydrates and to increase the quantity of fresh animal protein and fresh legumes (peas and beans) is emphasized.

We may not go all the way with the theory of the Public Health Service, remarks Dr. Isadore Dyer in the *American Journal of Tropical Diseases and Preventive Medicine* for May, 1916, but it is certain that the experiments done by Goldberger and his associates have conclusively demonstrated the importance of diet in the progress and in the relief of pellagra; we are not ready to accept the almost arbitrary dictum that diet alone causes pellagra; and we are emphatic in the belief that most cases of pellagra will get well under medication, irrespective of diet.

Opinion generally is divided in the question of the cause and treatment of pellagra, and so long as this is true, it is wisest to rest on the middle ground—make the diet well balanced and varied and at the same time cure the patient, with or without drugs, by whatever means will bring the result. The majority of pellagra cases are removed from the possibilities of institutional care and must depend upon the provisions of the houses—under ordinary conditions. It is important then that some other advice may be ready when the diet either does not produce results or where it cannot be maintained according to the rules laid down. The suggestion that is developed in considering a balanced diet as essential would lead to the conjecture that after all it is some one thing or some things lacking in the diet which affect assimilation. If the exact deficiency could be defined in chemical terms—the remedy might offer itself. The coagulability of the blood in pellagra is considerably reduced and the administration of gelatin seems to have corrected this to some degree. The nutritive element in gelatin may have additional value in this correction.

We still rely upon gelatin, citrus fruits, and hydrobromide of quinine in treating pellagra, and the large and growing majority of patients recovering under this régime agree that the disease disappears whether the treatment cures or not.

THE THERAPEUTICS OF CANCER.

For obvious reasons, the physician reaches out for every agent which offers the faintest promise to cure or ameliorate cancer. Generally, the remedial agents sought are of two kinds: Those which act on the malignant growth and those that are supposed to affect the cause. To the first belong the numerous escharotics, from arsenic to radium; to the second belong the remedies which affect metabolism or act on the etiological factor, whatever that may be. The action of escharotics is simple enough; the results, however, depend on so many factors that the outcome is uncertain. The main difficulty in the application of destructive agents is practically the same as is encountered in the removal of malignant growths by the knife, namely, that one of the chief characteristics of cancer is to break through natural barriers and infiltrate surrounding tissues; when it comes to attacking such a growth, the problem assumes a grave aspect. It is like conducting war against an enemy who employs guerrilla tactics. There is no way of attacking the outspreading cancer without at the same time injuring the normal cells which surround it. It is true that selective action is asserted for such agents as the Röntgen ray and radium, but the results obtained so far leave us more or less in doubt as to the soundness of that view. We may readily understand how a superficial, more or less circumscribed cancer can be successfully destroyed by the x ray or radium, or chemical escharotics, for that matter; but when it comes to deep seated cancers, particularly those with metastasis into the glands or distant organs, our imagination must suffer considerable strain to conceive a selective action of these agents on the cancer tissue alone. The argument generally advanced, that radioactive substances attack young or immature cells in preference to formed and mature cells, may be controverted by pointing out that in the tissues surrounding the cancer there is an abundance of newly formed cells. These are found in the areas of inflammation surrounding the malignant growths, in the course of regeneration which takes place after the destruction of the cancer, and in the normal blood and lymph streams. Moreover, it appears strange that the very agency which is supposed to destroy immature cells should also produce them, as is the case in x ray cancer. It seems reasonable to suppose that in cases in which the malignant growths are favorably influenced by the x ray or radium, the beneficial result is probably due to the autolysis induced by the stimulating effect of these agents and the consequent production of immunity, as a result of the action of autolysins on the surrounding tissue. This supposition is strengthened by the fact that a constitutional effect follows a deep therapeutic dose of the x ray.

The internal administration of drugs is thought either to influence metabolism or else affect the cause of cancer. Thus, Jaboulay employed quinine on the theory that the cause of cancer is a protozoon similar to the plasmodium of malaria and equally affected by the drug. He reported a number of cases of cancer successfully treated. The late Doctor Michailoff obtained brilliant results from the administration of iodides, maintaining that the latter possess an affinity for the cancer cells in which they produce degenerative changes. G. A. Garnak (*Roussky Vratch*, April 30, 1916) combined the ideas of Jaboulay and Michailoff and treated a number of cancer patients with quinine hydroiodide in doses of 0.5 gram three to four times daily. This preparation is found in commerce, but can be prepared extemporaneously by mixing 0.95 gram quinine hydrochloride with 0.4 gram potassium iodide. The author asserts for this preparation the disappearance of the malignant growth and of the glandular metastasis, as well as improvement in the patient's condition. In cancer of the esophagus, when

patients were unable to take food the administration of this preparation for one to two weeks so far improved their condition that they returned to work. Owing to his departure to the war, the author was compelled to interrupt his observations; his results, however, have been so remarkably encouraging that he hastens to communicate them in a preliminary report.

Garnak's statements appear extravagant and highly improbable, yet there is absolutely no harm in his method, and if it does prove another of the many will-o'-the-wisps we have been chasing so long, one more disappointment will make but slight difference.

THE PROGNOSIS IN ECLAMPSIA.

Such a serious outcome as diffuse or subcapsular hemorrhage or cerebral hemorrhage in cases of eclampsia is unfortunately only too well known, and the etiology is likewise demonstrated, but there is nothing more difficult in practice than to formulate a prognosis when dealing with a case of eclampsia. Usually the paroxysms appear during labor, rarely post partum, and other things being equal, eclampsia during labor is less serious than at other times, particularly at the end of labor, i. e., at the time when we can rapidly bring the delivery to a close. The emptying of the uterus is to be looked upon as a most favorable factor for recovery of the mother, and it is for this reason that to the majority of obstetricians eclampsia arising during pregnancy or post partum is far more alarming.

The prognosis will be all the more serious when eclampsia occurs early in pregnancy, as it indicates an acute and rapid intoxication. Writers differ as to the degree of gravity when eclampsia arises for the first time post partum. Tarnier considered it to be unusually serious because it indicated a severe and persistent intoxication, while, as pointed out by Boissard, the quantity of albumin contained in the urine is an element which, at present, has lost much of its significance from the standpoint of the prognosis. Many instances are recorded of death in which the urine contained no albumin, while on the other hand the intensity of the intoxication and the extent of changes in the liver were the most important elements in the case.

It is a well known fact that in women thoroughly intoxicated, the urine has lost its toxic properties, and the eclampsia will be all the more serious the greater the toxicity of the blood serum becomes. It is nevertheless true that if the presence of albumin does not represent a factor of gravity, it is an important symptom which should not be lost sight of and is the indication for a carefully directed treatment. It has been shown that the eclamptic accidents are due to phenomena making themselves evident generally by the presence of a considerable amount of albumin in the urine, the latter usually being scanty in quantity, and accompanied by hypertension and disturbances of vision.

For this reason a treatment by diet and drugs, having for aim to control the premonitory phenomena of the eclamptic paroxysms, has been employed, likewise frequent examinations of the parturient woman, but unfortunately, notwithstanding the great development of outpatient consultations for this purpose given in dispensaries and lying-in hospitals, many patients still seek advice only when they suffer from headache or from edema of the lower limbs. Even when they have timely warning, many women will not follow up the diet and other necessary hygienic treatment, so that with all care on the part of the physician disasters are still too frequent.

In considering the immediate prognosis it will be found convenient to divide the cases into three classes. In the first are placed patients in whom eclampsia has developed during pregnancy or just before labor. In the second class those in whom the accidents occurred during labor, and thirdly those who presented eclamptic disturbances after the child had been delivered. In each of these classes, primiparæ and multiparæ have been considered separately. The conclusions arrived at by Gauchon (*Thèse de Paris,* 1913), after a careful study of thirty-five cases, may, we think, be taken as representative. He found that the immediate prognosis gave a maternal mortality of 25.3 per cent. and a fetal mortality of forty-four per cent.

A woman who has had eclampsia in a former pregnancy may suffer serious accidents if she again becomes pregnant, as the return of the eclampsia is pretty certain, and under these circumstances Gauchon found that the maternal mortality was 2.8 per cent., while that of the fetus was sixty per cent.

THE FEELINGS.

The camps of the psychologists have been about equally divided in their interpretation of the relation of bodily changes to the mental processes which take place in emotional disturbances. There is the theory, older and more familiar, that the physical changes, such as quickening or slowing of the heart, blanching or blushing of the skin, laughing or crying, etc., are the results of nervous overflow following the mental disturbance brought about by the experience of the moment. The opposite theory, originated by Lange and favored by James, holds that our feelings are the psychic results which follow

bodily changes; that we are frightened because our knees tremble, are pleased with ourselves after we have blushed, etc.

Where conscientious thinkers are diametrically opposed in their ideas, it seems that the truth must lie in some middle course of thought, and recent physiological studies make it more and more clear that the physiological phenomena accompanying psychical changes which we call the emotions or feelings, neither precede nor follow, but are part and parcel of the same thing. What is of more and of very great importance, is that mind and body, psychical and physiological activities, meet on the common ground of the feelings; that certain disturbances of mind will produce certain feelings, that certain disturbances of body will also evoke certain feelings. A bodily injury may abolish appetite and hinder digestion, or affect blood pressure; and, on the other hand, distress originating wholly in the mind, from envy, worry, fear, or homesickness, may, in like manner, affect the appetite, retard digestion, and affect blood pressure. We have all had a general notion of such a relationship of mind and body, but recent physiological discoveries, especially in regard to the ductless glands and their relation to the nervous system, have made our knowledge of the matter more definite. We can begin to see from a scientific standpoint why so much bodily disturbance arises, in whole or in part, in the mind, and why a correction of mental conditions means so much to the health.

An attempt to explain why certain bodily disturbances accompany certain feelings—why the heart quickens with fright, why the digestive activities are stopped by fear, why we blush or turn pale on occasion, was attempted by Darwin, Spencer, and others. Some of these changes have seemed, on evolutionary grounds, to have been useful, but why any of them should have had a depressive effect is a mystery. Possibly they are a means of evolutionary correction by which Nature has arranged that those who think depressing thoughts—who tend to morbid states of mind—shall, just as those who transgress physical laws, be weeded out through the bodily depression which is sure to accompany such psychic states.

RESEARCH AS A NATIONAL DUTY.

Willis R. Whitney, in *Science* for May 5, 1916, makes a powerful and timely plea for national consideration of scientific research as a necessary function if the nation is to assume international leadership. While he speaks in particular of the national importance and rare opportunity in chemistry, his remarks apply with equal truth to science in general. He emphasizes the fact that the need and opportunity for research are always present, and that we "are retarded only by the inertia that is in us." He points out the commercial development of great industries from researches which at the time had apparently no practical bearing. He lays particular emphasis on what we, as Americans, are prone to forget or ignore, that commercial as well as intellectual and industrial leadership goes to that nation which can make a constant contribution to the sums of new knowledge. So succinctly has he phrased his argument, that its gist can best be given by assembling some of the key sentences.

"Scientific research, or research in the natural sciences and industries, might be defined as the pioneer work of the developed country. In this light it is easy to see that our turn has come. Not long ago our pioneer work was of another kind. It was opening up the undeveloped land. It was actively and well done. But the work must change because our requirements have altered. I want you to realize that in America we are going ahead in the future at a rate dependent entirely upon our preparation. Laboratories are a relatively modern thing. I want you to see that we must be foremost in systematic organized research, or we will be distanced by other countries which already well recognize the value of new knowledge. When so much of our material welfare, the condition and extent of our manufactures, the quality of our agricultural efforts, and the health of our people depend upon the rate of our acquirement of new knowledge, there ought to be much greater effort made along the lines of research than is at present the case. . . . We are living in the Garden of the Gods, but we are still eating grass. . . . I think the stadium should be the accessory of the laboratory, and that in reality a research laboratory is more compatible with the object of a university than is the more common training table. . . .

Research is preparation. It is preparing in our decade for the problems and the necessary work of the next. There are various kinds of preparedness. We are hearing a great deal about one of them nowdays—immediate preparedness for national defense. But there is a more farsighted preparedness that no one has adequately described and of which the building of new laboratories is a sign. This type is the very best type of preparedness if begun in time. The continued study of the secrets of nature, the uncovering of buried treasures which always seem buried just deep enough to develop the digger—these are the criteria of a strengthening nation. Research presents a way and the only certain way of insuring peace, of preparing successfully for defense, and of

being successful in war. It is the lasting, undeviating factor which has always dominated. . . .

When nothing new is being done by us it will be a sure token of our decay. When we stop increasing our experimental activities or fall for a considerable time behind the activities of other countries, we may expect to see our light become merely a memory, like that of Greece or Rome. I cannot look beyond the period when research shall cease in a country and still imagine that country a power in the world."

Whitney considers the university the natural parent and propagator of research and the spirit of research. His plea is indeed timely, and while medical science is no doubt in a healthy state as measured by his standard, physicians for that very reason can the more appreciate the need and the importance of what he has so admirably brought to attention.

A RURAL REMEDY FOR WHOOPING COUGH.

T. Mark Hovell, of London, at the repeated request of many friends, communicates to the *British Medical Journal* for July 1st a rural remedy for whooping cough which appears to be not known generally to the profession. It consists of peeling the cloves of garlic, as the segments of the bulb are called, cutting them into thin slices, and wearing them under the soles of the feet between two pairs of socks, for if placed next the skin the pressure produced by walking is apt to cause irritation. The garlic can usually be smelt in the breath within half an hour after the slices have begun to be worn, and the whoop and spasm usually disappear within forty-eight hours. The garlic should be worn for a week or ten days or longer, according to the severity of the case. Among the French Canadian *habitants*, we know that onions are used in exactly the same way. Garlic may also be administered by eating it as a form of bread sauce, made by chopping up the cloves when peeled, boiling them in milk, and mixing them with breadcrumbs.

News Items

American Association of University Professors.—It is planned to hold the annual meeting of this association in New York city on Friday and Saturday, December 30th and 31st.

The Washington State Medical Association, in convention, has elected Dr. George M. Horton, of Seattle, president for the year 1917. He will succeed Dr. J. M. Semple, of Spokane, who was elected a year ago and took the chair this week for the present year.

The Montana Medical Association at Miles City, July 13th, adjourned after a two days' convention. Kalispell was chosen as the place for next year's meeting and officers were elected as follows: President, Dr. J. A. Donovan, of Butte; first vice-president, Dr. Arthur Morrow, of Kalispell; second vice-president, Dr. R. H. Beach, of Glendive; third vice-president, Dr. Arthur Jones, of Butte; secretary-treasurer, Dr. E. J. Balsam, of Billings.

Eugenics Research Association.—At the annual meeting of the Eugenics Research Association held at Cold Spring Harbor on June 22d, Professor Adolf Meyer was elected president in succession to Professor J. McKeen Cattell. The association will join in the Convocation Week meeting of the American Association in New York at the end of the present year.

New Official Journal.—The Minnesota Public Health Association has begun to publish a journal, the first issue, the July number, just having come from the press. It will appear regularly the first of each month hereafter. Dr. I. J. Murphy is editor of the journal and executive secretary of the association. Requests for the publication should be sent to the Minnesota Public Health Association, Old Capitol, St. Paul.

Northwestern Medical Society.—At the annual meeting of the Northwestern Medical Society, at Long Pine, Nebraska, July 18th, the officers elected for the ensuing year were: Dr. G. O. Remy, of Ainsworth, president; Dr. E. T. Wilson, of O'Neill, vice-president; Dr. J. M. Tische, of Wood Lake, secretary; Dr. Thomas J. Lawson, of Long Pine, treasurer. Wood Lake was selected for the next meeting, on the last Tuesday in October, 1917.

American Medicopharmaceutical League.—A regular monthly meeting of the executive committee of this organization took place on Monday evening, July 24th, at 451 Forty-seventh Street, Brooklyn. Two papers on infantile paralysis were read and discussed. The next meeting of the committee will be held on Monday, August 28th. Dr. Ramon Guiteras, of New York, is president of the league, and Dr. Samuel F. Brothers, of Brooklyn, is corresponding secretary.

Award of the Albert Medal.—The Albert medal of the Royal Society was awarded, on June 29th, to Professor Elie Metchnikoff, two weeks before his death. "in recognition of the value of his investigations into the causes of immunity in infective diseases, which have led to important changes in medical practice, and to the establishment of principles certain to have a most beneficial influence on the improvement of public health."

Postponement of the Amalgamation of Medical Schools.—It is stated that the members of the United Medical Committee, in charge of the medical school of the University of Pennsylvania and the Jefferson Medical College, of Philadelphia, have agreed that it is advisable to postpone the consummation of the union agreed on by the plan adopted by the trustees of the two institutions, in order that further opportunity may be afforded for considering a number of important matters relative to the mode of administration of the new school, and have, therefore, determined that each of the schools shall conduct, separately from and independently of the other and of the United Medical Committee, the work of its college term for 1916-17.

Changes at the Rockefeller Institute.—The Board of Scientific Directors of the Rockefeller Institute for Medical Research announce the following promotions and appointments: Dr. Alphonse R. Dochez, hitherto an associate in medicine, has been made an associate member. Dr. Henry T. Chickering has been appointed resident physician in the hospital to succeed Doctor Dochez. The following have been made associates: Dr. Louise Pearce, pathology and bacteriology; Dr. Frederick L. Gates, pathology and bacteriology. The following have been made assistants: Dr. Oswald Robertson, pathology and bacteriology; Ernest Wildman, chemistry. The following new appointments have been made: Dr. Rhoda Erdmann, associate in the department of animal pathology; Dr. Rufus A. Morrison, assistant in medicine and assistant resident physician; Dr. John Northrop, assistant in the department of experimental biology; Dr. Jean Oliver, assistant in the department of pathology and bacteriology; Dr. Ernest W. Smillie, Fellow in the department of animal pathology; Dr. William D. Witherbee, assistant. Dr. Hardolph Wasteneys, hitherto an associate in the department of experimental biology, has accepted an appointment as associate professor of pharmacology in the University of California.

Gifts to Hospitals.—The will of Mrs. Helen C. Juilliard gives $50,000 to the American Museum of Natural History, $25,000 to Colorado College, $100,000 each to St. John's Guild and the Lincoln Hospital, and $50,000 to the New York Orthopedic Hospital.

The Guggenheim brothers, associated as M. Guggenheim Sons & Co. and in the American Smelting and Refining Company, have added $165,000 to their donations to Mount Sinai Hospital, making their total gifts in memory of their parents $665,000.

Announcement is made of a gift to the Johns Hopkins Hospital of the sum of $95,000 by Dr. Kenneth Dows, of New York. The money is to be devoted to the investigation of tubereulosis and the better teaching of physicians and students in the recognition and management of the disease and the care of the patients who seek treatment for it at the hospital.

The Lowell General Hospital, Massachusetts, has recently received a gift of $200,000 from Mr. Frederick Fanning Ayer. This sum is intended mainly as an endowment for the hospital.

Three gifts totalizing $57,600 have been presented to the Babies' Hospital, Philadelphia, during the past week. Of this sum, $50,000 is given anonymously by a prominent Philadelphia woman.

Typhoid Fever in Toronto.—In 1910, the death rate from typhoid in Toronto per 100,000 population was 40.8. In 1915 it was 1.9, leading all cities of 350,000 population and over in Ameriea. This represents a saving of 195 lives per annum, which, assuming that only one patient of every ten or fifteen dies, means the prevention of over 2,000 cases. The largest factor in the reduction of the rate is considered to be the chlorinating of the water supply, and its bacteriological examination six times a year. No milk typhoid has been in Toronto since 1912, owing to the requirement for pasteurization of all milk entering the city (except certified milk). Nor has there been any typhoid from oysters or raw vegetables. Contact infection has been discounted by circulars of information on typhoid and its spread and advocating inoculation. The danger of fly transmission has been considerably cut down by publicity campaigns against flies and by the abolition of outdoor privies. In examining the results of the epidemiological examination of the 151 cases of typhoid in Toronto for 1915, one of the most striking features is that sixty-nine of these cases were infected outside the city. Of the eighty-two cases infected in Toronto, thirteen, or more than fifteen per cent., were found to be due to either direct or indirect contact.

To Coordinate Poliomyelitis Research.—In order to enlist the active cooperation of the leading laboratory workers in this country in the study of the many problems presented in the epidemic occurrence of poliomyelitis, the commissioner of health last week invited the following well known pathologists and bacteriologists to meet in this city August 3d and 4th to consider the problems and to plan out a well coordinated series of investigations likely to effect their solution: Dr. George J. Adami, of McGill University; Dr. Charles Bass, of Tulane University; Dr. Ludwig Hektoen, of the University of Chicago; Dr. Paul Lewis, of Vanderbilt University; Dr. Francis W. Peabody, of Peter Bent Brigham Hospital, Boston; Dr. Milton J. Rosenau, of Harvard University; Dr. Theobald Smith, of the Rockefeller Foundation; Dr. Victor Vaughan, of the University of Michigan, and Dr. William H. Welch, of Johns Hopkins University.

Associated with these will be the following representatives of the prominent research laboratories in this city: Dr. William J. Elser, Dr. Simon Flexner, Dr. Emanuel Libman, Dr. Hideyo Noguchi, Dr. Charles Norris, Dr. William H. Park, Dr. Francis Carter Wood, and Dr. Hans Zinsser.

Not by spectaeular chance discoveries, but rather by painstaking investigations in which fact is added to fact, can it be hoped to secure control over poliomyelitis. With the foremost minds of this country at work and attacking the subject from many different angles the outlook for a successful outcome is encouraging.

Health Exhibit at Coney Island.—A health exhibit, for men only, designed to teach the important facts regarding venereal diseases, is now being successfully operated at Coney Island. Financed mainly by the New York Social Hygiene Society, the exhibit represents the cooperation of that society, the Brooklyn Hospital Dispensary, genitourinary department, and the department of health. A medical adviser is in attendance every evening; a demonstrator at all times. Judging by the number of visitors, their demeanor, the interest taken in the exhibit, and the questions asked, the enterprise is bound to exercise a wholesome educational effect. It is planned to show this exhibit in various parts of the city at the close of the Coney Island season.

Personal.—Dr. Walter Eugene Garrey, formerly connected with the department of physiology of Washington University, St. Louis, Mo., has been elected to the chair of physiology in the college of medicine of Tulane University, of Louisiana.

Dr. William S. O'Neill Sherman, of Pittsburgh, has started for Europe to make a special study of gangrene, tetanus, and amputation in war hospitals for the Rockefeller Institute.

Dr. Victor V. Anderson has been appointed to direct the medical department and psychological laboratory established by the city council of Boston on June 23d in collaboration with the municipal police courts.

Dr. S. D. Abrams, of Inwood, L. I., has been appointed deputy health officer of Hempstead, L. I., for Inwood and Lawrence outside of the incorporated districts.

Dr. Harry M. Lee has resigned as medical examiner of the city of New London, Conn.

Dr. Edwin P. Kolbe has been appointed superintendent of the new Suffolk County Tuberculosis Hospital, which will soon be ready for the admission of patients.

Dr. Edward Torrey, of Olean, N. Y., has been appointed medical superintendent of the Cattaraugus County Tuberculosis Hospital.

Reasonable Quarantine Regulations.—In a recent number of *Public Health Reports*, the text is given of the recent set of regulations drawn up by the Vermont State Board of Health, regarding the quarantining of children coming from the city of New York since the development of the present outbreak of poliomyelitis.

1. No child under the age of fifteen years shall reside in this State for a period of more than twenty-four hours without being reported by an attendant, parent or guardian, to the health officer of the town or city where such child is, provided such child has been in the city of greater New York since June 20, 1916.

2. It shall be the duty of every housekeeper, manager, or proprietor of every hotel or boarding house where such child is domiciled immediately to report such child, giving the name and age, to the health officer of his city or town.

3. Every such child shall be subjected to quarantine for a period of two weeks from the time such child was last in the city of greater New York.

4. The health officer of every town and city to whom such a child is reported shall immediately serve a written notice upon the head of the family in which such child is This written notice shall contain a copy of these regulations and an order signed by such health officer requiring such child to remain on the premises in which it is at that time for the specified time of two weeks after last leaving the city of greater New York.

5. Each health officer to whom such a child is reported shall require of the attendant, parent, or guardian of such child a certificate in writing, duly signed by a legal practitioner of medicine, certifying that the nose and throat of such child have been thoroughly washed with a solution of a teaspoonful of common salt in a pint of water once a day for a period of three consecutive days before the premises are released from quarantine.

6. No child under fifteen years of age shall enter any house so quarantined.

7. A placard containing the word "quarantine" shall be sufficient evidence to all persons that the premises are quarantined for the purpose of these regulations.

Nothing in these regulations shall be construed to prevent other members of a household in which there is a child as above described, who has left the city of New York since June 20, 1916, from attending to their usual occupations.

The owners, managers, or proprietors of hotels and boarding houses may place no restrictions on attendants or guests in their hotels or boarding houses further than the strict isolation of any children, as above described, from New York city, provided such children are isolated to the satisfaction of the local health officer and their noses and throats irrigated as specified.

Each health officer will see that a copy of these regulations with which he is furnished is conspicuously displayed in at least three public places in his town or city.

These rules and regulations will remain in force until further notice.

Modern Treatment and Preventive Medicine

A Compendium of Therapeutics and Prophylaxis, Original and Adapted

THE THERAPEUTICS OF A PHARMACOLOGIST.

By A. D. Bush, M. D.,
Department of Biology, Olivet College.

Thirty-first Communication.

LOBAR PNEUMONIA.

Aside from the uncertain use of antipneumococcic serum, the treatment of pneumonia is absolutely symptomatic. In such a self limited disease the physician's function is one of "watchful waiting," the nonuse of drugs often being the best therapy, although it takes a strong minded doctor to resist with reason the anxiety of his own heart, the importunities of the patient's relatives, and the obloquy and contumely of lookers on know-it-all; but the sooner physicians learn that, in the absence of specific remedies like quinine in malaria, drugs are to be used in well defined emergencies only, the better will be the status of medicine as a science. It might be well to add that an intimate knowledge of pharmacodynamics is prerequisite to the scientific treatment of disease.

Nature effects the cure; but sometimes a toxemia so handicaps nature that normal control is upset and artificial aid in the way of drug influence becomes imperative. In pneumonia the cardiac reflexes may be disturbed and require readjustment; in which case, as in typhoid, caffeine will restore force and volume, and digitalis will reestablish rhythm with increased volume at every contraction. If vagus control is deficient, small doses of aconite may be of assistance, but have to be carefully watched. A prominent textbook advises the use of strychnine, but, as stated before, there is no pharmacological evidence that strychnine has any direct effect on the heart; it is a marked stimulant of the spinal cord and might in this way bring about indirectly a greater call for blood in metabolism, but it cannot be called a true heart stimulant. Alcohol is also advised by some, and small doses might possibly be of benefit in conserving body tissue, but no dependence is to be placed on alcohol for any assumed cardiac influence, unless, indeed, depression of the heart is the end sought.

In pneumonia, a prominent writer says epinephrine may be used hypodermically to stimulate the vasomotor centre! So far as the pharmacologist is aware, epinephrine has no effect whatever on the vasomotor centre, but acts on the nerve terminations to the muscle coats of the bloodvessels or directly on the muscle itself. Moreover, if combating lowered blood pressure should be indicated, epinephrine would be an inferior agent here because of its fleeting action; caffeine would be much more efficient. But it must be borne in mind that the depressor condition is due to accumulating toxemia, and is to be combated by increasing the rapidity of elimination through saline injections and by speeding up diuresis and diaphoresis.

The use of oxygen seems logical whenever consolidation reaches the degree where alveoli and bronchioles are so compressed as to cause interference with diffusion. Pure oxygen, administered at this time, diffuses more rapidly to the furthermost air passages than does the more dilute oxygen of atmospheric air, and thereby advances gas equilibrium in the blood, restoring a normal proportion of oxyhemoglobin and preventing cyanosis.

In some robust patients, where the cardiac response to initial toxemia is so intense as to be dangerous, aconite in guarded doses usually relieves the temporary stress and saves the heart from permanent injury. Of course, the drug should be promptly discontinued as soon as physiological action becomes evident.

The sharp pleuritic pain usually introducing pneumonia is most readily dulled in consciousness by an opiate, supplemented by a sinapism over the affected area for its reflex stimulation.

The cough, unless unduly distressing, need not be treated, as it is nature's attempt to remove abnormal products from the respiratory passages. Various "stimulating" expectorants have been advocated, but there is no adequate evidence that any drugs excreted by the bronchial mucosa have any effect in increasing the fluidity of mucous secretions. Ammonium chloride is a drug that has been widely recommended, but without convincing proof that it is ever excreted through the lungs; if it does have a real effect on the mucosa it must be by direct contact, and should therefore be administered in the form of a vapor.

Some writers have advocated the administration of antiseptics, such as phenol, thymol (!), and mercuric chloride. They seem to have the idea that the drug, changed chemically in the alimentary tract, absorbed then into the blood stream, carried thence to the diseased tissue, still retains a selective toxicity for bacteria only; and possibly the history of arsenobenzol gives brilliancy to such an idea. But one of the great errors in the use of drugs has been the failure sufficiently to recognize that each drug is peculiar unto itself; and a second one is that of believing that the body is a great test tube wherein reactions will take place with the same definiteness and simplicity as in the little glass tube of the biochemist. If there be any truth in such ideas the first place to discover it may well be the laboratory; there at least errors in technical judgment bring consequences less serious, and being frequently checked are soon uncovered. Lack of adequate checking, whether at the bedside or in the hospital, has often been a fruitful source of precipitate deduction involving far reaching error.

Let the use of drugs in lobar pneumonia be sternly limited to undeniably definite indications; then let such only be used as will probably effect the desired end; see that the patient does not have to fight drugs as well as disease.

Critique of Present Methods in the Treatment of Infantile Paralysis.—H. Winnett Orr (*American Journal of Orthopedic Surgery,* June, 1916) suggests that braces in the treatment of infantile paralysis should never be employed until all the improvement possible from other measures is obtained.

Diagnosis and Treatment of Poliomyelitis.—Walter L. Barber (*Medical Record,* July 22, 1916) declares that prophylaxis is important, the patient should be isolated, all articles which may have become infected should be destroyed, antiseptic spraying of nose and throat should be practised, and hexamethylamine should be given as a preventive. Actual treatment of the disease comprises a preliminary dose of calomel, an ice bag along the spine, acetphenetidin to control headache, muscular pain and restlessness. Hexamethylamine with benzoic acid may be used in large doses with benefit in the active stage, while strychnine is to be given only after all inflammatory symptoms have subsided, and then in small continued doses. Galvanism and massage with muscle education are later used to restore atrophied muscles.

Clinical Importance of the Wassermann Reaction.—Eusebio de Oyarzabal (*Revista de Medicina y Cirugia Practicas,* June 28, 1916) states that this reaction appears usually five to six weeks after infection, rarely earlier. In the secondary stage it is positive in ninety-five per cent. of cases while of the tertiary cases only seventy per cent. give a positive test. Tabes gives eighty per cent. while general paralysis shows one hundred per cent. A positive Wassermann may return after it has been rendered negative, and this is due to a period of latency or to insufficiency in dose or duration of antisyphilitic treatment. To discover whether a negative reaction is permanent a small dose of salvarsan or neosalvarsan may be administered and this frequently will produce a positive test if any spirochetes are still present in the system because their destruction produces substances which render the test positive. In cerebrospinal cases it is advisable to do the test with the spinal fluid.

Treatment of Streptococcic Infection.—E. Dolphus Haysmer and W. L. Sucha (*Western Med. Review,* June, 1916) make a study of a large number of cases of so called grippe, finding the disease to be due to infection with a special strain of streptococcus. In the treatment of this infection, which included cases of grippe, rheumatism, neuritis, tonsillitis, adenitis, pneumonia, bronchitis, pleurisy, etc., the authors found no drug was of any curative value. Many, such as phenacetin, aspirin, etc., used to relieve symptoms, actually so depressed the patient as to hinder recovery and to prolong convalescence. Where it was absolutely necessary to relieve symptoms suitable drugs were used, but the cure of the condition rested entirely on the exhibition of autogenous or stock vaccines made from the particular strain of organism. Thorough elimination and the use of salol or hexamethylenatetramine were helpful adjuncts in the treatment of some of the cases.

Disinfection of the Nasopharynx in Meningococcus Carriers.—M. H. Gordon (*Brit. Med. Jour.,* July 1, 1916) reports that bacteriological tests showed that it was possible completely to disinfect nutrient plates by saturation of the atmosphere of the room in which they were exposed with a vapor of chloramine. Such a saturated atmosphere can be borne without damage and with little or no discomfort by persons entering the room for periods of five to twenty minutes. From these observations it was but a step to determine the possible disinfectant value of such a vapor in patients harboring the meningococcus in their nasopharyngeal tracts. Two patients were exposed to the vapor, and complete and apparently permanent disinfection took place.

Treatment of Scoliosis.—Edward S. Hatch (*Southern Medical Journal,* July, 1916) believes that the Abbott method gives far better results than any other, but the technic is so complicated that there are few men who put on the jacket as Doctor Abbott teaches, even though they use his frame. It takes from three to six corrective jackets to effect a cure, each jacket being worn about seven weeks, or so long as one can further correct the position by the application of felt pads. While we strive to overcorrect our cases it is not always possible to do so, but in practically every case we place the children in a nearly normal position. After the patients' attitudes are corrected, exercises are used daily for many months. These must be given at first by a competent instructor and later carried on at home. If the patients do not carry out the exercise treatment, they will gradually relapse.

Vaccine Therapy in Typhoid Fever.—Petrovitch (*Bulletin de l'Académie de médecine,* June 13, 1916) reports the results obtained in military practice in Serbia with vaccine treatment in typhoid fever. Whereas, among 1,020 cases treated by ordinary measures the mortality was 12.8 per cent., among 2,270 other cases subjected to vaccine treatment, without the administration of cold baths, it was only 2.7 per cent. Small doses—five to fifty millions of typhoid bacilli killed by heat—proved as efficacious as larger ones. Where results were slow in appearing, and in complicated cases, the dose was reduced rather than augmented, and such reduction proved essential for benefit in these patients. Very toxic cases, often in subjects greatly exhausted and already weakened by dysentery or cholera, proved in no way refractory to the treatment except when the eliminatory functions were impaired. A few of these patients, however, died in convalescence, rather from extreme cachexia and anorexia than from myocarditis. In cases with renal or myocardial complications, and in general when elimination is in abeyance, Petrovitch counsels great reduction in the dose, lest uncertain or even unfavorable results ensue. The dose in general should be based, first, on the rule that all pronounced local and general reactions are to be avoided, and second, on the general progress of the case, in particular the temperature, with due attention to the functions of the liver, kidneys, skin, respiratory apparatus, and intestine. Small doses are of advantage in avoiding excessive excitation of the tissues as well

as an excessive production of antibodies, with resulting massive liberation of endotoxins and stress on the eliminatory organs. Sometimes the pulse became soft when the temperature dropped and the general condition improved. This peculiarity was noted at times after the first vaccine injection, but especially after the second or third, the patient, however, presenting no other manifestation of cardiovascular disturbance. The habit was accordingly formed of giving a little caffeine internally after the second injection. This always improved the pulse and counteracted the weakness previously noticed.

The Transplantation of Ductless Glands.—O. T. Manley and David Marine (*Jour. A. M. A.*, July 22, 1916) found as the result of many experiments in this field, carried out on rabbits and including most of the ductless glands, that homotransplants of ovarian or splenic tissue almost invariably underwent prompt absorption. In the case of the ovary the lipoid luteal cells, however, often persisted. The rate of absorption varied widely and seemed to depend largely upon essential variations in the hosts. While autotransplants of spleen also were always absorbed, those of ovary usually survived and grew. The reaction of the thyroid to transplantation was more extensively investigated than that of other tissues; it was found that autotransplants of this gland uniformly survived and grew. On the other hand, homotransplants almost always ultimately underwent absorption, though in a few cases such transplants survived and grew. Absorption took place as early as the tenth day and was delayed in other cases as long as a month or more. When the first homotransplant was absorbed, subsequent ones always suffered the same fate and in progressively shorter periods of time. The rate of absorption could be modified by altering the condition of the host or that of the thyroid tissue used. Thus, when iodized thyroid tissue was transplanted into an iodized host the rate of its absorption was greatly reduced. This suggests that it may be possible to alter the reaction of the host toward other tissues by the use of one or more or their specific chemical constituents. The therapeutic future of transplantation depends upon the solution of this problem of favorably influencing the viability of homotransplants.

Vaccine Treatment in Streptococcal Puerperal Fever.—Chalmers and O'Farrell (*Journal of Tropical Medicine and Hygiene*, April 1, 1916) report from the Sudan two cases of successful vaccine therapy in puerperal fever due to streptococci of the fæcalis group. Such cases, they find, are peculiarly suitable for vaccine treatment in that they represent local infections, without evidence of septicemia in blood cultures from a vein. In the first case antistreptococcal serum and cleansing of the uterus had caused improvement, but this was only temporary, and even after administration of a 5,000,000 dose of the autogenous vaccine the patient grew obviously worse. A 200,000,000 dose was then given, with resulting prompt drop in the temperature and complete recovery. In the second case, high fever had existed six days, with feeble and very rapid pulse, and on the third day after this douching of the uterus had to be stopped owing to refusal of the patient's friends to have it done. A 5,000,000 dose of the same vaccine as that made from the first case caused slight improvement and subsequent 50,000,000 and 200,000,000 doses, complete recovery. Vaccines evidently may be of great service in such cases in raising the resistance of the body against the germs which may be passing from the uterus into the blood stream in quantities so small that, while killed in the blood, they do not cause enough reaction to increase antibacterial powers. If necessary, a polyvalent antistreptococcic serum and saline injections may also be used to combat and remove the toxins. In a severe septicemia the vaccine method would, of course, be useless. In cases where it does promise benefit, doses sufficiently large should be used, 5,000,000 to 10,000,000 being merely an initial experimental dose given to ascertain the condition of the patient as regards the organism. The first therapeutic dose should be not less than 50,000,000, and should preferably be followed in a week or less, according to the symptoms, by a 200,000,000 dose and later, by additional doses as required.

Syphilitic Elephantiasis of the Genitals and Its Treatment.—A. Ravogli (*Lancet-Clinic*, June 17, 1916) found the specific spirochete one of the most effective organisms in causing elephantiasis of the genitals. The condition was always the result of an extended ulcerative process of tertiary syphilitic nature. The possibility was not excluded, however, of the superadded presence of tuberculosis which, either locally or in the general system, might have given the ulcers a more destructive character. The syphilitic process, as a whole, tends to induce lymphatic stasis, as illustrated in the indurative edema of the initial lesion, which often complicates also the constitutional lesions of syphilis. Its cause is found in a specific inflammation of the lymph vessels, causing occlusion of the lymphatics by coagulation of the lymph. In early syphilis this specific edema subsides under treatment, but in the late period, when affecting the genitals, grows persistently. Internal mercurial or arsenical medication gave no results in Ravogli's cases of genital elephantiasis. According to the general condition small doses of calomel or gray oil injections, potassium and sodium iodide, and tonic preparations were given. Externally, no local application was of benefit, though bathing with a mild solution of mercury bichloride or sodium bicarbonate proved useful in relieving tension, and pads of bichloride gauze in the irritation of friction. It was found that, to obtain good results, the extensive ulcers must be curetted until the normal substratum is reached. Dressed with iodoform gauze or one in 2,000 bichloride gauze, the ulcers then heal in a short time, leaving smooth, regular scars. For the elephantiasis, surgical removal of as much as possible of the hypertrophied tissues is best. In a case of enormous growth of the clitoris, the organ was removed. In involvement of the labia majora, the elephantiasic tissues in the centre of each were dissected out and the upper skin layers saved and sewed together. In the male as much as possible of the organs was saved. The wounds always healed readily. After two or three years no relapse had occurred.

Treatment of Paralysis agitans with Parathyroid Gland.—William N. Berkeley (*Medical Record*, July 15, 1916) states that he wrote on this subject in 1910, and that he is still convinced that the disease is due to a deficiency in the parathyroids. The parathyroid extract used in doses of one fiftieth grain for three to six months produces marked improvement.

Dose of Digitalis.—J. T. Halsey (*Southern Medical Journal*, July, 1916) advocates the administration of full doses in order to secure full therapeutic action in less than twenty-four hours, and the reduction of the dose as soon as the first signs of digitalis effects appear. After sufficient of the drug has been given, in most cases relatively small doses of fifteen to thirty minims a day are usually enough to maintain the desired effect. The administration of full doses is safe only if the patient is kept quiet in bed and under close and accurate observation by competent observers.

Hay Fever.—W. Scheppegrell (*Medical Record*, July 15, 1916).—Plants causing this disease are those the pollen of which is borne by the wind instead of by contact or by insects. Increased susceptibility after an initial attack is due to anaphylaxis by absorption of pollen proteins. It must be remembered that microorganisms play an important part from the lowered resistance of the nasal mucous membrane. Removal from an infected locality may not necessitate going more than a half mile from areas with pollinating weeds. In using pollen extract it is important to select the proper pollen by conjunctival or skin tests, and when this treatment is not successful autogenous vaccines may be tried made from the bacteria in the nasal secretions.

Mixed Vaccine against Typhoid and Cholera.—A. I. Bielousova (*Roussky Vratch*, April 20, 1916) investigated by experiments on animals the effect of mixed vaccines by determining the presence of agglutinins, deviation of complement, and bacteriolysins in the serum of the animals thus immunized. It was found that mixed immunization produces agglutinins against both antigens, that these agglutinins increase with the number of injections, and that the typhoid agglutinins, whether in mixed or separate immunization, are stronger than those of cholera. The accumulation of the agglutinins in the blood depended on the dose rather than the number of injections. A given dose produced a certain amount of agglutinins whether administered singly or by repeated injections. The complement-fixation was found to both the typhoid and the cholera antigens, and the degree of fixation was the same with mixed as with separate immunization. The same observation was made with regards to bacteriolysis, except that the bacteriolysis of the cholera bacilli appeared sooner and was more marked. The general conclusion reached by the author is that in view of the possibility of immunizing the organism against more than one infection, mixed vaccines should find a wider application.

Scarlet Red in Gastric and Duodenal Ulcer.—Julius Friedenwald and T. F. Leitz (*Medical Record*, July 22, 1916) give their results in the use of this drug in forty-five cases of peptic ulcer. These cases, together with thirty-seven already reported by the writers, justify the conclusion that scarlet red may be given in doses of fifteen to twenty grains, three or four times daily, with great benefit.

Panautogenous Vaccines in Lung Affections.—Alfonso F. de Alcalde (*Revista de Medicina y Cirugia Practicas*, June 8th, 1916) reviews his results in 186 cases. Of fifty-two cases treated by autoserotherapy eighteen were cured, twenty-eight were relieved, and six ended in death. Of ninety-eight cases treated by panautogenous vaccines fifty-eight ended in recovery, thirty-four were improved and six terminated fatally. Of the 186 cases treated, all but thirty-five were tuberculous.

Intestinal Paresis with Special Reference to Pituitrin in Its Treatment.—A. J. Colton (*Buffalo Medical Journal*, July, 1916) reports the case of a woman with double pneumonia whose abdomen was greatly distended and tympanitic, the diaphragm crowded upward, so that breathing was extremely embarrassed, and she was evidently dying. Her blood pressure had fallen forty points. One half c. c. of pituitrin was injected very slowly into the median cephalic vein. "Within thirty seconds there was the most remarkable effect I ever witnessed on a human being, the expulsion of large quantities of flatus with a large liquid stool that nearly filled the bedpan. The abdomen in less than three minutes was in normal condition." The patient recovered.

Epilepsy.—Francis X. Dercum (*Jour. A. M. A.*, July 22, 1916) finds many different causes which may produce the symptoms commonly denoted as epilepsy, and since, therefore, the condition is not a disease entity, there cannot be any specific treatment for it. Each case should be subjected to the most thorough investigation, including serological tests and the family history. Treatment will depend largely upon the result of such study, but the chief question is what to do in the treatment of the residual group of patients who present evidences of the deteriorating, defective, and autotoxic organism. The first requisite is the prescription of a life as nearly physiological as possible, without mental or physical strain and in the country on a farm or in a camp. This often greatly reduces the frequency of the seizures, which is probably mainly due to increased oxidation of waste and toxic substances. In addition, however, the diet should be modified by the exclusion of red meats and reduction in the carbohydrate intake so that as little strain as possible will be thrown upon the liver and the several endocrine glands. Elimination should be free through the alimentary tract, the kidneys, and skin, which can be secured by adjustment of the diet, the use of mild saline laxatives, drinking copiously of water, and indulgence in daily warm sponge baths. Drugs may be required for the control of the seizures, and the best seems to be one of the bromides for this purpose, but to secure the greatest effects from the bromides there should be a simultaneous withdrawal of the chlorides. Lastly, in some cases the administration of small doses of thyroid (one eighth to one quarter grain three times a day) for long periods often seems to raise the patient's physiological level with marked benefit.

Two Cases in Which the Lateral Ventricle Was Opened.—H. F. Wooffenden in the *Lancet* for May 20, 1916, states that of 200 cases seen two were treated by extraction of foreign bodies from the lateral ventricle with complete recovery.

Operative Treatment of Empyema.—Howard Lilienthal (*Medical Record,* July 15, 1916) advises x ray examination in all cases to aid in selecting the type of operation. The aspirating needle should not be used until within a few hours of operation. Ether anesthesia is to be avoided usually because of its irritant action; local, regional, or nerve blocking anesthesia or nitrous oxide and oxygen narcosis may be employed. The operations are minor and major thoracotomy, resection for encapsulated empyema, and the old resection method.

Rest and Exercise in Tuberculosis.—Thompson Frazer (*Southern Medical Journal,* July, 1916) summarizes his paper by saying: A thorough knowledge of the principles of rest and of exercise must underlie the treatment of tuberculosis. Neither exercise nor rest is to be prescribed offhand, but so long as there are symptoms pointing to an overworked body, rest is indicated, the character and amount to be carefully prescribed; with improvement, exercise slowly increased provides the safest means of regaining health and strength. Exercise must be increased gradually, as a single act of overexertion may delay recovery months or years, or even preclude it. The transitional period should be under careful medical supervision until the patient is able to withstand without harm more than he will be called upon to endure when he takes up active work.

Treatment of Constipation in Women.—Justin Herold (*Lancet-Clinic,* May 13, 1916) reiterates the fact that results obtained in this condition with nonmedicinal measures are far superior to those obtained with drugs. The diet for these patients should contain about six and a half times as much vegetable matter as meat, with a liberal proportion of starches, sugars, oleaginous foods, and water. The best laxative foods are porridge, cornmeal mush, cracked wheat, syrup, honey, molasses, milk, sugar, whey, buttermilk, coffee (for some patients), apples, peaches, pears, prunes, cherries, figs, dates, raisins, preserved or stewed fruits, butter, bacon, and salad oils. Regular indoor exercise should be encouraged, and may take the form of calisthenics, Swedish gymnastics, basket ball, fencing, or bowling. Irrigations should be used chiefly for healing local lesions, clearing out putrefying food, and to stimulate cardiac and renal action. In chronic atonic constipation retained enemas are useful to provoke evacuation without the help of an irrigation. The best results are obtained from daily injection of from one to three pints of water at 70° to 80° F. into the colon. In spastic constipation, on the other hand, warm or hot water enemas (105° to 110° F.) are preferable to cold. Water taken by mouth is effectual when drunk in one half glassful amounts every hour or two. One to one and a half glassful should be taken on rising. Massage is generally most beneficial when practised over the abdomen and lumbosacral spine; general manipulations may, however, be administered when a universal toning up is needed. Effleurage, pétrissage, friction, tapotement, and vibration may all be applied with advantage. In obstinate atonic constipation the séance should last from twenty minutes to an hour, and the massage given at least once daily for a prolonged period. In intestinal autointoxication vibratory treatment has given satisfactory results; it is contraindicated, however, in the presence of anal fissure, inflamed and ulcerated hemorrhoids, ulcers, carcinoma, stricture, or acute catarrh of the rectum or colon. Galvanism, a very broad electrode to the spine being used, is of value in atonic constipation, while general faradization is indicated where there is autointoxication and general debility. Among drugs, physostigmine is an especially useful remedy in atonic constipation. Constipated women at the change of life suffering from headache, vertigo, and flatulence can be afforded much relief with it, administered with or without nux vomica. Rhamnus purshiana is also a valuable drug. When very large doses of it are required, a necessity for combining with it such drugs as iron, strychnine, belladonna, hyoscyamus, or calomel is indicated. In pregnancy, enemata and vegetable pills containing podophyllin or rhubarb are chiefly relied on by Gant. Aloes and myrrh relieve dysmenorrhea in constipated women. During menstruation, there should be cessation of massage, vibration, and cold hydrotherapy; evacuations may be secured temporarily with pills or enemata.

Resection of the Ovaries for Microcystic Disease.—J. A. McGlinn (*American Journal of Obstetrics,* March, 1916) asserts his belief that the microcystic ovary should, in the majority of cases, not be treated by resection. This type of ovary is found in practically all cases of uterine retrodisplacement that has lasted a number of years. The thickening of the ovarian capsule due to chronic congestion results in a studding of the ovary with retention cysts, the increased weight of the organ then causing it to prolapse into the posterior cul-de-sac, where it is subject to pressure by the full rectum or displaced uterus, with resulting pelvic pain and tenderness. Partial excision of such ovaries does no good, as the thickened capsule over the parts remaining cannot be removed, while the handling of the organs at the operation causes further capsular thickening, and the scar tissue formed is likewise unfavorable in its effect. Most cases thus treated are, in fact, made worse, a secondary operation becoming necessary to remove the remaining ovarian tissues. The author, therefore, no longer resects such ovaries, but simply punctures the cysts which are upon the surface of the organs, handling the latter as little as possible. The uterus, if displaced, and the ovaries are then restored to their proper position by a suitable operation. Subsequent treatment is applied to relieve or prevent pelvic congestion. Where an ovary is found so diseased that it is not amenable to the foregoing treatment, it is removed. It is often possible, however, to save both ovaries, and usually at least one ovary is in a sufficiently good condition to be preserved in its entirety. Good results were obtained by this method, and no further operations have been necessary.

Miscellany from Home and Foreign Journals

Aminoacid Nitrogen in the Blood of Children.—C. J. V. Pettibone and F. W. Schlutz (*Jour. A. M. A.*, July 22, 1916) made determinations of this nitrogenous constituent of the blood of children under a variety of conditions of health and disease and showed that, while the average figure was somewhat below that for adults, there was no consistent or characteristic variation in any of the diseases studied. Further, fever did not cause any typical variation in its amount.

Prognosis in Volvulus.—In *American Journal of Surgery*, June, 1916, is published a clinical lecture by D'Arcy Power on volvulus. With regard to prognosis he says that it is at the present time extremely unfavorable; he hopes that the practitioner of the day will improve it, just as he and his contemporaries have improved the prognosis of intussusception. Improvement rests entirely with present day medical men, for it depends upon early recognition, and upon early recognition depends the success of operative treatment.

A Symptom in Extrauterine Gestation.—H. J. Lehnhoff (*Archives of Diagnosis*, April, 1916) considers a severe, cutting pain in the lower abdomen, ocurring while the patient is at stool and, as nearly as can be ascertained, at the time when the abdominal muscles contract in assisting to empty the bowel, a practically pathognomonic symptom of extrauterine gestation. Of eight cases, six presented this symptom. Ischiorectal, tubal, or large appendicular abscess fails to produce the symptom, and the pains of rectal, pelvic, or bladder growths, or those of ureteral calculi, kinked ureter, or twisted cyst pedicle, do not resemble it; nor does it occur in acute perforations of the stomach, intestine, gallbladder, or appendix.

Diabetic Coma in Alcoholics.—E. Schulmann (*Presse médicale*, June 5, 1916) reports two cases of diabetic coma in heavy drinkers and sets forth the symptomatic peculiarities. Both his patients, brought into the hospital semicomatose, manifested mental and physical agitation, necessitating forcible restraint, together with auditory and visual hallucinations, talkative delirium, tremor (especially in the upper extremities), and fever, the temperature reaching 39.2° C. in one case and 38° in the other. In analogous cases previously recorded by Dreschfeld, stress was laid on headache, vertigo, embarrassed speech, and motor incoordination, followed by complete coma and death in twelve to twenty-four hours. In Schulmann's cases, however, signs of delirium tremens accompanied those of diabetic coma until death. The respiratory disturbances typical in diabetic coma were also noted. The attack of acute alcoholism in these cases is secondary to the coma. Death took place on the fourth day in both instances. The prognosis in the combined condition is particularly grave. Simultaneous alkaline treatment of the diabetic acidosis and treatment with ammonium acetate and injections of camphorated oil are indicated.

Intestinal Toxins and the Circulation.—D. T. Barry (*Lancet*, July 1, 1916), in the course of an investigation of the actions of the excretory toxins on the neuromuscular mechanism of the heart, found certain toxic substances in both the small and large intestines which exerted a deleterious action on the heart when introduced into the circulation. Such substances, when present in abundance, may be absorbed and produce cardiac symptoms and damage. The cause of these toxic materials has not been determined, and the nature of the substances is unknown. That absorption of the materials does occur is indicated by the frequent occurrence of heart block and arrhythmias in persons with intestinal disorders.

Mixed Typhoid and Paratyphoid Infections.—A. Chantemesse and A. Grimberg (*Presse médicale*, June 15, 1916) assert, after a careful study of 160 cases by refined laboratory methods, that ordinary typhoid fever is not always due to invasion by the typhoid bacillus alone. Among thirteen fatal cases examined, the typhoid bacillus proved to have been the sole infective agent in only two cases; in seven instances, the paratyphoid A organism was also present, and in the remaining four, the paratyphoid B bacillus. The paratyphoid infection may be added either from the outset or later in the course of the disease. Blood cultures under these conditions reveal the various organisms, and serum tests show the several specific agglutinins arising from these organisms distinct from the group coagglutinins. Comparison of the temperature and specific agglutinin curves of patients reveals the influence on the former of invasion by fresh types of typhoid germs. To such secondary invasions are to be ascribed the temperature fluctuations often termed recrudescences, relapses, the amphibolic stage, abnormal prolongation, etc. Recovery from ordinary typhoid fever commonly confers an immunity which includes one or both paratyphoid infections. Vaccination against the typhoid bacillus alone, however, yields no general immunity of this kind. Vaccination with a heated vaccine consisting of a mixture in approximately equal parts of the three typhoid germs, as recommended by Castellani about ten years ago, is thus an entirely legitimate procedure. Since blood cultures practised in the course of typhoid fever yield positive results in only about one half the cases, the diagnostic procedure of choice in this disease is the continued observation of the agglutinins in the blood by a macroscopic, precise method involving study of emulsions of the typhoid and paratyphoid organisms (to be described in a later paper). The presence in a patient's blood of an agglutinin due to previous typhoid fever or antityphoid vaccination does not interfere with this procedure, the curve of such an agglutinin remaining unchanged, while that of the agglutinin of a disease running its course at the time shows the usual phases of ascent and descent. Where a multiple typhoid infection is diagnosticated, a corresponding mixed vaccine should be used in its treatment.

Changes in Muscle After Nerve Section.—J. N. Langley (*Lancet,* July 1, 1916) offers two theories to explain muscular wasting following the division of a nerve: 1. There are special nervous impulses presiding over its nutrition; 2, the wasting is due to lack of use. Neither of these theories is free from objections and the first has received but little support. The second is largely overthrown by the fact that vigorous induced contractions of the muscles do not prevent wasting. Recent studies have shown that the muscle from which the nerve supply has been severed promptly passes into continuous fibrillary contraction. These contractions occur many times a minute and are continuous, so that a simple explanation of the muscular wasting is exhaustion due to overactivity rather than to disuse atrophy.

Mixed or Hybrid Diseases.—P. Remlinger (*Paris médical,* June 10, 1916) groups under the term "mixed diseases" conditions characterized, not simply by coexistence of two affections, e. g., typhoid fever and erysipelas, which run a parallel course without modifying each other, but by a dovetailing of two affections which results in distinct changes in the symptomatology, course, and duration of each, rendering a complete diagnosis often exceedingly difficult. Mixed diseases are to be set apart from mere mixed infections, which, while frequent, cannot be diagnosticated clinically and are often simply laboratory surprises. Mixed diseases are most easily produced where two conditions involve the same organ or system and begin simultaneously. Yet Joltrain has called attention to cases of mixed typhoid fever and diphtheria without false membrane formation in which peculiarities of the temperature curve and constitutional reaction, vomiting, facial pallor, albuminuria, asthenia, small and rapid pulse, redness of the velum palati, and slight edema of the uvula led to a suspicion of associated diphtheria, which, in turn, was confirmed by bacteriological study and the effects of antitoxin therapy. Mixed diseases thus far studied have been far fewer than the multiplicity of theoretical combinations allow. The best known mixed condition is the so called typhomalarial fever, which Vincent has definitely shown to be due, in a few instances at least, to combined presence of the plasmodium and the typhoid bacillus. Cases of combined Malta fever and typhoid fever have been reported, and in northern Africa a hybrid of typhus and relapsing fever, probably due to simultaneous infection from body lice, is encountered. A hybrid of typhus and typhoid fevers in prisoners abundantly infested with lice, characterized by sudden onset, extreme prostration, a confluent eruption of maculæ which failed to disappear upon pressure, death on the third to the sixth day, and at autopsy a soft, enlarged spleen containing typhoid bacilli, has been encountered recently in France. A typical hybrid disease is that consisting of typhoid fever and dysentery; it is not uncommon among troops in active service, and at times appears in epidemics. In such instances the diagnostician remains for some time in doubt whether the case is one of typhoid fever accompanied by greenish stools, tenesmus, and pains in the large intestine, or of malignant dysentery with fever, dry tongue, headache, sleeplessness, and feeble heart action. Bacteriological studies plainly show a coexistence of the diseases. Such hybrid diseases show a marked predilection for individuals subjected simultaneously to multiple causes of infection and to causes of lessened general resistance, especially in emigrants, pilgrims, and in soldiers on war service. In ordinary practice, however, a frequent hybrid is that of combined tuberculosis and syphilis, manifested especially by involvement of the lymph glands (syphilostrumous adenopathy), cornea, skin (hybrids of syphilis and lupus) and even the lungs. Measles and scarlet fever are also at times so superimposed as mutually to destroy their identity, the initial nasal, ophthalmic, and bronchial catarrh of measles being soon followed by a diffuse raspberry color or roseate eruption upon which are engrafted flat or slightly raised macules of a darker shade. Where the throat is but slightly involved, such an eruption leads to much diagnostic difficulty. General desquamation follows the mixed eruption.

Fractures in Children. — Jacob Grossman (*Medical Record,* July 8, 1916) concludes from a study of 200 cases that the commonest cause of error in diagnosis in children is incompleteness of fracture when it is of the fissure or torsion variety. The most constant diagnostic sign is localized bone or "pencil" tenderness. These incomplete fractures require the same treatment as complete fractures, with a less prolonged period of immobilization. The tendency to heal is more intense than in adults and the immobilization period is shorter; refusal of a child to use a limb for any length of time should arouse suspicion of fracture; proper retention is as important as proper reduction. Early massage, active and passive movements are of importance.

On the Application of Tablets of Calcium Chloride to the Sterilization of Drinking Water in the Army.—Ch. D. Archipiantz (*Roussky Vratch,* April 30, 1916) discusses the utility of calcium chloride tablets, containing one mgm. of available chlorine in each tablet, for the sterilization of drinking water by the soldiers. He found in his experiments that the efficiency of these tablets depends not only on the kind of the germ, but also on its resistance to the action of germicides. The cholera spirilla will be destroyed very readily. On the other hand, some of the other microorganisms require a much longer contact. Also, in addition to the factors of contact, the amount of available chlorine, and the resistance of the microorganisms, the quality of the water must be taken into consideration. In the presence of a considerable amount of organic matter in the water, a larger quantity of chlorine is required. Also, the amount of chlorine will be influenced by the reaction of the water. In the author's experiments, two mgms. of chlorine to the liter of water killed the cholera spirilla in ten minutes; the typhoid bacilli were destroyed in two hours and forty minutes; the dysentery bacilli in two hours and fifty-five minutes; and the colon bacilli in three hours and five minutes. In view of the uncertainty of the action of chlorine when thus applied to the sterilization of drinking water, the author is of the opinion that these tablets should receive limited application, namely, when other means of sterilizing the water are not available.

Epidemic Poliomyelitis: Symptomatology and Diagnosis in the Acute Stages.—Francis R. Fraser (*Boston Medical and Surgical Journal*, July 20th) gives the following symptomatology of this disease:

1. *Preparalytic and general symptoms.* The parents as a rule state that there was a sudden onset of fever, with drowsiness, general weakness, loss of appetite or vomiting, and perhaps irritability and restlessness, which frequently is ascribed to a mild disturbance of the digestion. Fever is always present at first. The temperature usually is from 101 to 103° F., swinging slightly and gradually subsiding in a few days, but may be 104° or 105° F. at the onset as well as in a few cases before death, and readings of 100° F. for many weeks are not unusual. When the symptoms indicate lesions in the upper part of the central nervous system it may be 103 or 104° F. for three or four days and then end in crisis. The pulse rate follows the temperature. Gastrointestinal disturbances are usually present and may predominate during the first few days. A slight catarrh of the upper air passages, with somewhat reddened tonsils and pharynx is not uncommon, but an acute tonsillitis would suggest another diagnosis. Frequently the first symptom is heaviness and drowsiness, accompanied by irritability when roused which is in striking contrast to the heaviness seen when the patient is left alone. The child is cranky and restless, and frequently there are jerking movements of one, or of several parts, or of the whole body. A diffuse generalized sweating is common in very severe cases, and in the early period before definite paralyses are seen, there is apparently a general weakness of the entire musculature. There is much diffuse pain and tenderness, and pain in the back of the neck and in the back is an important symptom. The patient prefers to lie on one side so that the head may be tilted slightly back, or on his back with a pillow between his shoulders so that the head falls back. Kernig's sign is not present as a rule.

2. *Spinal fluid symptoms.* The changes in the spinal fluid are not characteristic of this disease alone, but are useful in differentiating the disease. The cells are increased in number and there is an increase of the globulin content. Cell counts of over 1,000 per c. mm. are rare, counts under 100 are more common. During the first few days polymorphonuclear cells and cells with irregular nuclei may be numerous, but after the first week the increase is due almost entirely to cells of the lymphocytic type. The globulin increase is found in one half of the fluids during the first week, and in an increasing proportion to the third week. In the first week nearly all the fluids show abnormalities in cell count, in globulin content, or in both; in the fourth week about one half are abnormal; then the proportion falls off rapidly. The fluid does not clot, is sterile, and no organisms can be found after it has been centrifugated.

3. *Blood.* The blood gives no help, as there is no change in the number of red cells, and the number of white cells is within the limits of normal variations.

4. *Disturbances of the motor system.* Paralysis may involve almost all of the musculature, or be limited to a single group, or a muscle. It may be severe, producing a permanent complete paralysis, or be mild, causing a partial paralysis or a temporary weakness, so that a most thorough examination is necessary, in which every muscle must be tested. Much information as to the condition of the muscles can be gained from an inspection of the attitude of the patients and of the limbs, and by testing the tone of the muscles on passive movements.

5. *Disturbances of reflexes.* As in the case of the paralysis it is the asymmetry of these disturbances that is characteristic. Reflexes may be exaggerated one day and absent the next, may be lost gradually, or they may be exaggerated in one part and absent in another at the same time.

6. *Disturbances of the sensory system.* Pain and hyperesthesia are present, but in little children an accurate examination of sensations is impracticable. If exact methods of estimating muscle power and sensation were available, it is possible that many abortive cases which show none but the preparalytic and general symptoms, would show changes, and that many cases of doubtful diagnosis could be cleared up.

7. *Diagnosis.* In the preparalytic period and in abortive cases this depends to a great extent on the presence of an epidemic and association with other cases. Under these circumstances a sudden onset of fever, gastrointestinal symptoms, and perhaps pain would demand a careful examination for signs of stiffness of the neck and back. If there is any suspicion of a meningitis, the condition of the spinal fluid will clear the diagnosis in most cases. The differentiation from a gastrointestinal upset is most difficult, but the spinal fluid is normal, diarrhea is more usual than constipation, and vomiting is more persistent. The other common infectious diseases begin similarly, but in them the pain and hyperesthesia is usually absent, the spinal fluid probably is normal, and a rash develops. Acute rickets is easily mistaken, but the spinal fluid is negative, and a pronounced enlargement of the liver is not found in poliomyelitis. The onset is different in tuberculosis of the hip. In acute rheumatic arthritis, the tenderness is confined to the joints, and in poliomyelitis there is no synovial effusion or swelling of the joints. Meningitis due to the meningococcus, pneumococcus, influenza bacillus, streptococcus, and staphylococcus, gives a spinal fluid with cell increase due to polymorphonuclears, and the organism can be found in smears and can be cultivated. In tuberculous meningitis, and in syphilitic meningomyelitis, the spinal fluid is similar to that of poliomyelitis and the clinical findings are not differentiated until the case has been watched for a few days. The finding of tubercle bacilli, evidence of tuberculosis elsewhere in the body, and the absence of paralysis of muscle groups in a very sick child help to differentiate in the one case; the signs of congenital syphilis, and the enlargement of the liver and the spleen help in the other. Acute poliomyelitis is probably mistaken for cerebrospinal meningitis more often than for any other disease, but the rash, the photophobia, and the characters of the spinal fluid should differentiate it.

Proceedings of National and Local Societies

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Tenth Annual Meeting, Held at Saratoga Springs, May 16, 17, and 18, 1916.

The President, Dr. W. STANTON GLEASON, of Newburgh, in the Chair.

SECTION IN GYNECOLOGY AND OBSTETRICS.

(*Continued from page 238.*)

Gynecological Surgery in Hysteroneurasthenic Patients.—Dr. H. S. CROSSEN, of St. Louis, said there were three questions to be asked: 1. Was operation indicated? 2. If indicated, what was the preferable time for operation, before or after the course of neurological treatment? 3. When operating, should more or less conservatism be practised than in an individual with a normal nervous system?

In regard to the first question, where the pelvic condition was seriously depressing the general health through blood loss or pain due to lesion, the lesion must be removed, irrespective of the coexisting nervous disease. Cases had to be carefully studied and there were two types to consider: First, those in which the chief symptom was pelvic pain, with a lesion which accounted for this, and, second, those in which the symptoms were extrapelvic, but were supposed to be due to intrapelvic lesions. In neurasthenic patients, where pain was of secondary importance, operation was contraindicated, but if prolonged treatment with all ordinary measures failed to relieve pain, then operation was indicated. In the second group operation would relieve only so far as nutrition was affected by the lesion, and general nervous irritation allayed.

As regards the second question, when operation should be performed, it had better be done before neurological treatment. Rest in the hospital might give a good start to recovery; but if the influence of the lesion was questionable, the neurological treatment should come first, as with treatment operation might be rendered unnecessary.

Dr. LEROY BROUN, of New York, asked what treatment should be given to these neurotics? If there were no local findings, the cases were undoubtedly for the nerve specialist, but if there were distinct local findings from the point of view of the gynecologist, we must attend to them, but patients must be also treated neurologically. He believed that it was generally considered that there were merely steps between the hysterical patients and the neurasthenic patients, and the manic depressive types. It was simply a question of gradation. Whatever affected the general health of these patients affected also their nervous and mental status, and the gynecological surgeon must remove whatever lesion might have a bearing on this. Among 500 patients operated upon at the Manhattan State Hospital for the Insane, thirty-two were so much improved in general health that they were discharged as temporarily cured.

Dr. GORDON GIBSON, of Brooklyn, stated that many a woman was operated upon for pelvic conditions without regard to the psychic lesion. The ordinary surgeon or gynecologist could not grasp all the features of neurasthenia. The question to be asked was, Was the patient neurasthenic? Often a doctor saw a patient who told a long story of symptoms, and upon examination there did not seem to be sufficient diseased tissue to account for the disease. There might be some, but not of great importance. The question arose, Was the mild lesion influencing an exhausted nervous system, or were the symptoms entirely due to morbid tissue? If a man had not sufficient experience with psychical disturbances, he must have his neurological colleague see the case with him. It was quite true that the pelvic disease might be keeping up the nervous symptoms. Those might be intensified by loss of sleep, by chronic pain, or other exhausting factors. The history of the neuropathic or psychopathic patient, often disclosed a slight pelvic lesion.

Dr. R. T. FRANK, of New York, said in connection with the removal of the ovaries there was a method by which they could work without being too radical. The patient could have x ray treatment of the ovaries for some time and in this way the menstrual flow could be reduced to every third or fourth month, and the result of the treatment could be carefully noted. It was then time to consider the effect of operative interference.

Dr. SAMUEL W. BANDLER, of New York, believed there were no cases of pelvic disease not associated with some ductless gland disturbance. Pain was often reflex; the pain had no effect, but the condition of the patient was affected through the medium of the ductless glands, of which the ovaries and the thyroid were the most important. The nervousness was produced by the metabolic change. For that reason, the nervous patient was often better after an operation if they did not promise too much. A nervous woman could be told that the operation would probably help her condition, and if she wanted to belong to that large and important class of women who liked to sit in the parlor and talk over her operation with her friends, she had better be allowed to do so. In cases of constitutional dysmenorrhea the woman should be operated upon.

Dr. MARY G. POTTER, of Rochester, many years ago heard it stated by orthopedic surgeons that ninety-five per cent. of patients suffering from pelvic pain had flat feet. A teacher came to her with severe backache and abdominal pain, and was operated on for gallstones, but after the removal, she had the same symptoms. It was found that her feet were severely calloused and that the arches were flat. With the relief of this condition her symptoms disappeared. In another patient for whom an Alexander operation was done without improvement of symptoms, the feet were found severely calloused and the interior arch was flat. Treatment of the flat foot relieved all the nervous symptoms.

Dr. RICHARD R. SMITH, of Grand Rapids, Michigan, said the first important point was the necessity of a thorough study of the physiology of the pelvis, and the second was the relation of the pelvic re-

flexes to the neuroses. This would give a tangible basis on which to work. The gynecologist should act in consultation with the neurologist rather than the reverse. The former could help the latter by bringing the patient into a better physical condition.

Practical Aspects of the Internal Ovarian Secretion.—Dr. William P. Graves, of Boston, in considering the general bearings of this subject from the standpoint of gynecology, presented the following conclusions: 1. That in genital atrophy there might occur abnormalities of great importance to the gynecologist. 2. Circulatory disturbance of the external genitals, such as kraurosis and furunculosis of the vulva, might be greatly relieved or cured by the administration of ovarian extract. 3. Ablation symptoms were in the great majority of cases markedly relieved by administration of ovarian extract. 4. After hysterectomy vasomotor symptoms followed the transplantation of ovarian tissue and also leaving the whole ovary *in situ*, similar in degree and frequency to those following total ablation of the ovaries. 5. Functional amenorrhea in the young was often relieved by ovarian extract. 6. Extracts of the whole ovary were more efficacious than extracts of corpus luteum.

Dr. Samuel W. Bandler, of New York, agreed that the extract of the whole ovarian tissue was more efficacious than that of corpus luteum alone. He did not use corpus luteum extract. In reference to operations done in the later years of a woman's life, such as hysterectomy for fibrosis uteri, he did a vaginal hysterectomy, and if the ovaries looked normal he left them behind. He did not think it was wise to leave an inflamed ovary, for that would necessitate a second operation. If, after the operation, the patient was put on ovarian extract, it would prevent the recurrence of hot flashes. If his surgical judgment so dictated he was never afraid to remove both ovaries, and ovarian extract was begun at once.

Dr. R. T. Frank, of New York, protested against the statement that in ordinary hysterectomy it was unimportant if the ovaries were removed. In his experience, if the ovaries were left behind, there was much less likelihood of those troubles. It would not do to say, he left the ovaries or he took away the ovaries. The question was, did the operator leave the ovaries with good circulation? It was often found that even removal of the uterine artery would have an atrophic effect on the ovary. Unless an ovary and tube were left in a healthy condition, it would do no good to leave them; but unless the woman was close to the menopause, it was certainly important to leave an ovary with good circulation.

Five Hundred Cases of Pelvic Infection with End Results.—Dr. John O. Polak, of Brooklyn, said that a study of results of conservation of ovaries with resection or suspension, had caused them to swing toward more radical treatment, because it was useless to conserve ovulation without menstruation, and a conserved ovary behaved badly in cases of pelvic infection. It tended toward cystic formation and pain, and the trauma and circulatory disturbance disturbed the functional activity. No operation should be undertaken during the acute stage of infection, or when exudate was present. Bacteriology of the infection was important, because different organisms had different histories. Gonococcus and streptococcus infections differed widely, the former causing suppurative salpingitis, oophoritis, and peritonitis; the latter lodged almost always in the parametrium. In nonoperative cases, patients suffered from postabortive infections, and were very ill on admission. They were put in a high Fowler position, a rectal tube was inserted, ice bags were applied to the lower abdomen, and absolute gastric abstinence was enforced. Later, whenever possible, the patients were kept in the fresh air. Some cases required drainage by posterior colpotomy. Of 104 patients, 101 recovered.

Another class of 168 women desired to be cured of sterility. They presented a similar history of poor health since marriage, and they had been pregnant; birth was followed by pain, leucorrhea, or some menstrual anomaly. Examination of the husband generally showed infective cocci in the prostatic urethra. In few of the women were gonococci found. Sterility, dyspareunia, and leucorrhea were the symptoms. Of the 168 cases, only twenty could be relieved of sterility. The next class consisted of 107 women with gross pelvic masses, in whom infected structures were removed, yet the menstrual function was conserved. Eighty of those women remained well. Others returned for reoperation for metrorrhagia, menorrhagia, or cystic ovary. The fourth group comprised eighty-nine cases, in some of whom a portion of the ovary was conserved. Those results were among the most disappointing and fifteen had been operated on again, as headaches, hot flashes, sweats, etc., and burning pain over the ovary had followed. The final class comprised thirty-two women in whom such pathological destruction had taken place that conservation was out of the question. Those women all recovered. Climacteric symptoms were prominent in four, while the others had good general health. One important conclusion was that total extirpation was better than conservation of vitally impaired structures.

Infection of the Uterine Appendages; Sequelæ; Nonsacrificial Treatment.—Dr. E. E. Montgomery, of Philadelphia, said infection of the appendages was favored by any condition that favored congestion of the pelvic structures. Those conditions lowered resistance of the tissues and promoted nurture of the infecting elements. The infection spread by the mucous surface and was accentuated by the disturbing influences of menstruation. The most usual organisms were gonococcus, staphylococcus, streptococcus, colon bacillus, tubercle bacillus, pneumococcus, and influenza bacillus. Gonococcus was most superficial in its effect, but prepared the ground for other organisms and was thus more baleful in its work. Nature endeavored to protect herself by closing up the tubal ends against the invader. Sometimes the infection was so virulent as to prevent this, sometimes so slight that it did not take place. The peritoneum was sometimes directly infected through the wall, causing an extensive abscess which involved the tube and ovary. Such effects necessitated the sacrifice of the organs. The causes of infection might be impure sexual rela-

tions, want of care in labor or abortion, severe pelvic inflammation from infection, in which sometimes relief might be obtained by drainage through the vagina. In acute infections the plugged up tube became a sac filled with serous, bloody, or purulent contents. All the adjacent structures might become involved, and the ovary became a mere abscess cavity filled with pus. Should such a case fall into the hands of a surgeon who advocated prompt surgical treatment for all pelvic inflammation, the sacrifice of the appendages must be made. That procedure broke down the barriers raised by Nature, and even more dangerous extension might take place. The limited number of gynecological beds in hospitals and the urgent desire of patients to go home, frequently hurried the resort to surgery, but the large number of women who had had pelvic peritonitis justified careful revision of the procedures.

Dr. F. F. Simpson, of Pittsburgh, said every one now recognized that Doctor Montgomery's cases would go on to recovery with a mortality of less than one per cent. from acute disease. Twenty years ago the mortality was due to the activity of the bacteria present at the time of operation. These organisms were just as virulent today as then. A great mistake was made in placing on the same plane disease of the appendix and other hollow viscera on the one hand, and of the the tubes on the other. He would emphasize the extreme wisdom of avoiding operation until all inflammatory exudate had been completely absorbed, as its presence was Nature's positive statement that there were virulent organisms present which she feared to admit into the circulation, and if Nature feared to admit them, the surgeon should be afraid to spread them on the peritoneal surface.

Dr. Thomas J. Watkins, of Chicago, believed that for years they had been making mistakes and calling more of these cases gonorrheal infection than was necessary. He believed that varieties of streptococcus infection that had been present in throats and mouths had given increase of infections in the peritoneum. He had had two cases of salpingitis secondary to throat infection. The knowledge that had been gained in the treatment of tuberculosis should be utilized in the acute pelvic infection. The outdoor treatment was as important as in tuberculosis.

Dr. Edwin McDonald Stanton, of Schenectady, said that cystic degeneration of the ovaries following operation had been mentioned. His own experience in an analysis of 100 cases, operated in for salpingitis, was that in sixty-seven one or both ovaries were left, in thirty-three both ovaries and tubes were removed. In the sixty-seven there were three cases of cystic degeneration, and one of the cysts had to be removed by secondary operation. The other conditions cleared up in a short time.

Dr. Hiram N. Vineberg, of New York, said when the uterus and tubes had to be removed the question was whether to leave a portion of the ovary or not. The patient was very much worse off if they left a portion of the ovary. It was liable to undergo cystic degeneration. If, when doing an operation for fibroid uterus, he could leave enough uterine tissue behind and enough ovary to enable the woman to go on menstruating, it would do no good, but if the uterus had to be entirely removed, it was a question whether what they could retain of the ovary would prevent menopause symptoms.

Resection of the Pars interstitialis in Disease of the Fallopian Tubes, with the View of Preserving the Uterus.—Dr. L. K. P. Farrar, of New York, said this was an attempt to deal with the problem of diseased Fallopian tubes, as frequently presented to the surgeon. Drainage, whenever possible, should be done, but often both tubes were too much involved, and leaving the stumps led to metritis and discharge, or possibly adhesions in the pelvis. The pouchlike form of the pars interstitialis lent itself particularly to the continuance of infection, which was frequently gonococcal. Occasionally with the removal of the infected part the uterus was found to recover, and so the resection of the entire tube was considered. The ovaries were to be removed only when absolutely necessary. Twelve cases were cited with good results following this procedure, and the patients returned to menstrual habit. The question of the use of the uterus after removal of the tubes was then considered. The series of changes taking place in the mucosa of the uterine wall during the menstrual cycle were discussed. Rightly considered, menstruation was found to be an ultimate excretory expression of internal secretory phenomena, of the whole organism, and not merely localized to the uterus and annexa. The difficulty of adjustment of a woman's life, after the removal of this periodical outlet, was touched upon, and Doctor Farrar ended by quoting the argument of Dr. William Polk, in 1893, in opposition to Lawson Tait and Robert Battey. He had said: "I can say that the woman has the right to have the operation tested. None of the patients I have operated on have died. . . . The operation is a simple one, and I can assert that it is efficacious. . . . My wish is simply to give the woman a chance to retain organs which she values if we do not."

Accidental Hemorrhage and Its Treatment.—Dr. James K. Quigley, of Rochester, N. Y., discussed the opinions on the frequency of this condition and its treatment. Many writers considered it very infrequent, but in a small service he had had experience of four cases, in which there had been a coincident albuminuria. Williams, in 1915, published a monograph reporting two cases in which he found microscopical infiltration of the uterine wall with blood, due to arterial changes with thrombosis. It seemed probable that toxemia caused both hemorrhage and a nephritis, the latter being the effect rather than the cause. The symptom was usually sharp, constant, abdominal pain, sometimes followed by collapse. When the hemorrhage was concealed, and not free, it seemed to occasion more shock to the patient. The uterus was extremely tender and the fetal heart difficult to locate. Rupture might occur into the amniotic sac. The danger of a post partum hemorrhage later was present, and the patient might die in shock. The operator should be ready to pack the uterus, as in the external hemorrhage cases the shock was proportional to the blood loss. In these cases the mortality was the highest

for both mother and child, of any obstetrical complication, being variously estimated by different writers, but apparently averaging eighty per cent. for the mother and seventy-three per cent. for the infant. Cæsarean section often proved the best means of delivery, but in severe uterine bleeding hysterectomy had sometimes to be resorted to in order to save the patient's life.

Dr. G. G. Ward would like to say a word. He had had a case a few months before of external hemorrhage. The patient was a primipara, twenty-seven years of age, in poor general condition. She had evidence of Graves's disease, though it was apparently quiescent. She had slight exophthalmos and enlarged thyroid. She was waiting in the hospital until term, and at term she started in labor. The head was engaged in the pelvis when almost immediately she began with a profuse hemorrhage. She was attended by an assistant, who thought it was a case of placenta prævia, but there was no evidence of this; it was purely external hemorrhage. On careful consideration of the circumstances—the woman being a primipara, and having no dilatation of the small canal—Doctor Ward decided to do Cæsarean section. The case had a good result, the child and the mother both recovering. The cause was found to be an interesting one. It was shortening of the cord, not a short cord, for it was wrapped about the body three times. There was a typical battledore placenta and the hemorrhage was mechanical, the cord being so short that it caused a pull on the edge of the placenta where the hemorrhage came from. If operation had not been quickly done in this case, and if they had waited to deliver the child by the vaginal route, both child and mother would have been lost.

Dr. William Brown, of Rochester, would like to call attention to one point of diagnosis in a doubtful case. Most of the grave cases were definite, but Williams had called attention to the mild cases where bleeding was going on. That was one of the most valuable diagnostic aids. These cases after extreme hemorrhage might still have slow pulse, out of proportion to the amount of hemorrhage. Here, if a hemoglobin estimation was done quickly, it would be of great value. Moderate bleeding would bring down the hemoglobin to sixty or seventy very quickly.

Doctor Quigley was glad that Doctor Brown had spoken of hemoglobin estimation. Blood pressure was also important. He had not taken time to mention the mortality in ten cases of Cæsarean section. All the mothers recovered, and the fetal mortality was fifty per cent., which was better than the average.

Some Mistakes in the Diagnosis of Ectopic Gestation.—Dr. C. C. Lytle, of Geneva, New York, said that very divergent opinions had been expressed on this subject, some saying that forty per cent. of hospital cases were diagnosed incorrectly, and that fifty per cent. of private physicians failed to recognize the symptoms until after hemorrhage had occurred. Physicians were not sufficiently alert to discover the condition, which was frequently mistaken for acute appendicitis. There was abdominal pain, vomiting, rigidity and often overdue catamenia. Often other conditions, such as pyelosalpingitis, hydrosalpinx, gallstone disease, cholecystitis were mistaken for ectopic gestation. In some cases the symptoms were not so severe as in acute appendicitis. Considerable suspicion should be attached to a menstrual flow from five days to a month overdue, and the character and amount of the flow should be observed carefully. Pain was present in eighty per cent., and a great diversity of symptoms which made diagnosis a difficult matter.

Dr. A. B. Miller, of Syracuse, said physicians of the present day were better educated to recognize the symptoms than in the past, although the specialist saw more of those cases than other men because the cases were referred to him as soon as met with. It was a difficult matter to diagnose ectopic gestation before rupture, although there might be certain characteristic symptoms. If the patient was under observation, and then rupture occurred, the physician might well know that something definite had taken place, but clinical pictures differed so materially that the physician had to reach conclusions by the physical findings.

Dr. William M. Brown, of Rochester, could not agree that the diagnosis should be made in eighty or ninety per cent. before rupture in ectopic gestation. A dispensary patient came in with a typical subjective history of ectopic gestation. There was a somewhat overdue period, with irregular and diminished flow, and other evident signs. Sharp lancinating pains were beginning. There was a perfectly well defined mass on the left side of the uterus, closely associated with it. It seemed perfectly plain that it was an extrauterine sac. He made a diagnosis and tried to induce the patient to come into the hospital. Twenty-four hours later, the neighbors telephoned that the patient was worse, and later the husband telephoned that she was dying. An ambulance was sent and the patient was examined in the ward by the physician and by the intern, all agreeing with the diagnosis. The patient was put on the table and the abdomen opened, and the tube found empty. There was a great deal of confusion and a cry of unnecessary operation. Twenty-fours hours later, the woman passed a fetus from the uterus. It was an extrauterine gestation with tubal abortion, and the mass felt less than three hours before the operation; still the operation was not necessary.

The Treatment of Procidentia uteri.—Dr. George Chandler, of Kingston, New York, said the treatment for this condition was often of no avail unless aided by a suspension apparatus. The uterine ligaments were powerless to hold up the perineum. He had been doing the operation of Kocher as modified by Murphy, in the Trendelenberg position, with a low transverse incision in the crease above the pubis. The recti were separated down to the pubic bone; the uterus was pushed up from the outside through the vagina; if very small, it was pulled up and turned to the right. The peritoneum was sewed tightly round the vagina to shut off the peritoneal cavity. The skin and superficial tissues were pushed upward from the fascia, the fascia was stitched together with catgut, and skin and superficial tissues with silkworm gut. The uterus was let fall into this bed and sutured, and the incision was

closed. The tubes and ovaries might be freed from the uterus and dropped back into the pelvic cavity. Following this operation the patient might have pain in the bladder for some weeks, but the technic was simple and the repair good. It was necessary to do the operation as near the pubic bone as possible in order to avoid hernia. This operation had given good results after two and a half years. It should not be done until after the menopause.

Dr. A. B. Miller, of Syracuse, said this operation would have a recognized place, but they must not lose sight of the etiology of prolapse. The physical findings in the pelvis were many and no one special operation would fit all cases. The position of the abdominal contents had to be considered, also that cases should be treated differently before and after the menopause. The tendency to various operations changed from time to time. Doctor Watkins did not now do his vaginal operation as often as formerly, and the Murphy button technic was not so much used, as surgeons found they could do better with sutures. The technic had to be varied according to the case and not vice versa; in other words, the pattern had to be cut according to the cloth.

Dr. George Gray Ward, of New York, would like to know what Doctor Chandler did in a case where the uterus had an interstitial fibrosis. Had he had any experience with the Mayo operation for prolapse? The operation that he had described was not always successful, as was shown in cases after a number of years where the cervix had been firmly fastened to the abdomen. There occurred elongation of the cervix with traction on the vaginal wall below. The increase in the size of the uterus was due to traction on the cervix.

Letters to the Editors

ADRENALINE PER OS.

St. Louis, *July 21, 1916.*

To the Editors:

Dr. Leland Boogher's letter (issue for July 8th), in which he mentions my advice to exhibit adrenaline, fifteen minims in water, for colicky pains, would impress the reader as if adrenaline was an analgesic; in your note you call attention to the fact that adrenaline per os has been believed to be inert. It is certainly true that per os it has no systemic effect, but it acts locally. Adrenaline stimulates the sympathetic nerve which, antagonistic to the vagus, induces relaxation of the smooth fibres of the intestinal canal (excepting the three sphincters), while it constricts bloodvessels. It had been observed lately in von Pirquet's clinic in Vienna that in bacillary dysentery adrenaline per os (given to control hemorrhages) would relieve pain promptly, but temporarily, its action lasting about one hour, when the dose had to be repeated. There was, however, no rise in blood pressure nor any other indication of stimulation of the sympathetic—it had not been absorbed. The local effect seems to induce a further (reflex?) action upon the entire length of the intestinal canal, to wit, relaxation (plus spasm of the pyloric, ileocolic, and anal sphincters). It is therefore indicated where such an effect is desired. The response seems to travel also along the bile ducts, relieving a gallstone colic, if not due to inflammation or ulceration. It seems to relieve also some cases of gastric crisis. The same result is attained by intravenous or hypodermic application, only that then a systemic effect would appear which might be contraindicated. A similar local action minus the systemic is observed in inhalation of vaporized adrenaline in bronchial asthma. So the old rule still stands, amended by observation of local manifestations. George Richter, M. D.

A WARNING TO WHOM IT MAY CONCERN; THE TREATMENT OF INFANTILE PARALYSIS.

New York, *July 26, 1916.*

To the Editors:

Since the publication of my Reflections on Predisposing Factors in Infantile Paralysis in the issue for July 29, I have had a talk with Doctor Edward Anthony Spitzka, who assured me that he fully endorsed all that I had to say in that article, including my criticism of the use of adrenaline. This conversation was brought about by the receipt of the following note from Doctor Spitzka:

Dear Doctor Talmey:

I cannot help dropping you a line of approval of your article in the New York Medical Journal today. To the bushel baskets full of ovaries, removed twenty-five years ago, some are attempting to add vats full of tonsils; and —if they could—would add all Peyer's patches.

Edw. Anthony Spitzka.

63 East Ninety-first Street, July 29, 1916.

On Friday evening, July 21st, a prominent daily newspaper published "ten treatment hints for paralysis cases." Among them were the following two: "antiseptics of throat and nose" and "intraspinal injections of adrenaline every six hours." I wish to warn parents and practitioners against these two remedies, which I consider a direct danger to the afflicted children. By applying antiseptics to the nose we should merely be driving infectious material into the ear and into the other accessory nasal cavities. The injuriousness of torturing a child every six hours has been exposed by me in an article which will soon appear in a prominent medical journal. One adrenaline injection may be tried, although the efficacy in children of this mode of treatment is still very doubtful. But to torture a child every six hours would create an injury, chiefly psychical, which could not but diminish the child's chance for recovery. I suggest that this mode of treatment be applied only in monkeys and in afflicted children of physicians who advocate it. When they see the pitiful strugggle of their helpless darlings against their periodical—period six hours—tortures, they will become converted.

In order to bring this warning before the public as soon as possible I applied, on Friday evening, to six great publishing offices, but failed everywhere. On Sunday morning I wrote to the newspaper in which I had read the "ten hints." but so far even this paper has not printed the warning, and I doubt if it will.

I wonder why a subject that concerns every family should fail to reach the public's eye when the most unimportant events and views find some publisher. I further wonder whether the prices of antiseptics and of other remedies have gone up, or are about to go up, soaring high. Max Talmey, M. D.

51 West 126th Street.

SODIUM VERSUS AMMONIUM SALICYLATE IN INFANTILE PARALYSIS.

New York, *July 29, 1916.*

To the Editors:

It was with great interest that I read the special article, Infantile Paralysis, by Dr. Beverley Robinson, in the New York Medical Journal for July 15, 1916, on the treatment of this disease, because since the appearance of the epidemic I have given attention to what should be done in such cases, as the present means are insufficient in the first stages, where destruction of the gray matter in the spine goes on rapidly.

The remedy I should choose is one similar to that proposed by the author, only in a different chemical combination and in greater strength. The dose for ammonium salicylate is 0.25 gram, whereas it is one gram for sodium salicylate, according to the pharmacopeia; and as I believe that the effect depends largely upon the quantity of salicylic acid circulating in the blood and entering all cells and tissues, I prefer the latter salt to the former. If anyone thinks it would be better to administer pure salicylic acid, he will find that this is injurious to the whole alimentary

canal and that the acid is soon converted in the body into its sodium salt.

I remember the time when salicylic acid was introduced into the medical armamentarium. The renowned chemist, Kolbe, of Leipzig, through large production made its widespread use possible, and advocated it for internal use as a substitute for carbolic acid, which, at that time, was much employed in surgery, but could not be given internally on account of its poisonous properties. Another remedy belonging to the same group, thymol, cannot take its place either, as its dose is only 1.125 gram.

Experiments with the salicylates were done mostly in 1875 and 1876 by Dr. E. Bälz, at that time assistant in the clinic of Professor Wunderlich, at Leipzig, and later professor of medicine at Yeddo and physician to the Emperor of Japan for twenty-five years.[1] He tried to replace hydrotherapy in typhoid fever by large doses of sodium salicylate, four to six grams once or twice a day (the maximum being twelve grams daily) or eight to ten grams through the rectum, and reported drops in the temperature mostly of 5.4° F., but also of 11° F. and even 11.7° F., without dangerous symptoms, only exceptionally collapse, but no *exitus lethalis*. The duration of the fever and its course were about the same as in cases treated with baths, and the mortality also was four to six per cent.[2]

We now know that sodium salicylate is practically useless in the treatment of typhoid fever; however, we know also that it accomplishes a good deal in polyarthritis rheumatica, for which it was first recommended by Stricker and is nearly as specific as quinine in malaria. And as it is proved that the former disease is also an infectious one, it is obvious that the salicylic salts have an effect on infectious germs in our body, and it is worth while trying them in a disease of contagious character, the remedy for which we are still seeking. Small doses, therefore, do not seem to be right, but rather as strong a solution should be brought into the blood as can be given without danger. In order to determine whether the doses given by Doctor Bälz are not too large in our climate and different surroundings, I—my weight is a little over 150 pounds—took four grams of salicylate of sodium one morning, in doses of one gram every half hour, and the same quantity in the evening of the same day, amounting to eight grams within twelve hours without disagreeable symptoms, except a slight buzzing in the ears and slightly poorer hearing on the next day and with hardly any influence on temperature, pulse, or respiration.

TABLE OF DOSAGE.

If the weight of a 1 year old child is about 23 pounds, the dose for the day would be gram 1.250, or grains 20.

If the weight of a 2 year old child is about 26 pounds, the dose for the day would be gram 1.375, or grains 22.

If the weight of a 3 year old child is about 29 pounds, the dose for the day would be gram 1.500, or grains 24.

If the weight of a 4 year old child is about 32 pounds, the dose for the day would be gram 1.625, or grains 26.

If the weight of a 5 year old child is about 35 pounds, the dose for the day would be gram 1.750, or grains 28.

If the weight of a 6 year old child is about 38 pounds, the dose for the day would be grams 2.000, or grains 32.

If the weight of a 7 year old child is about 42 pounds, the dose for the day would be grams 2.250, or grains 36.

If the weight of an 8 year old child is about 46 pounds, the dose for the day would be grams 2.500, or grains 40.

If the weight of a 9 year old child is about 51 pounds, the dose for the day would be grams 2.750, or grains 44.

If the weight of a 10 year old child is about 56 pounds, the dose for the day would be grams 3.000, or grains 48.50.

It should be given in four doses, two in the morning, half an hour apart, and two in the evening the same way. In case of threatening collapse hypodermic injections of camphor dissolved in oil ought to be given freely.

As regards other procedures in combating infantile paralysis, I am unable to offer any suggestion, for instance about hexamethylenamine. Injections of adrenaline into the spinal canal, proposed by Doctor Meltzer at the meeting of the New York Academy of Medicine, July 13th, may prove to be the best of all the means yet proposed.

OSWALD JOERG, M. D.

[1] *Archiv der Heilkunde*, 1877, pp. 60 and 344.

[2] When I was in charge of the same ward at the Leipzig Hospital, previous to Dr. E. Bälz, there were no deaths in 120 consecutive cases, all treated with hydrotherapy, but more energetically.

Book Reviews

Cerebellar Abscess: Its Etiology, Pathology, Diagnosis, and Treatment. Including Anatomy and Physiology of the Cerebellum. By ISIDORE FRIESNER, M. D., Adjunct Professor of Otology and Assistant Aural Surgeon, Manhattan Eye, Ear, and Throat Hospital and Post-Graduate Medical School, New York, and ALFRED BRAUN, M. D., F. A. C. S., Assistant Aural Surgeon, Manhattan Eye, Ear, and Throat Hospital, Adjunct Otologist, Mt. Sinai Hospital. With ten full page plates and sixteen illustrations in the Text. New York: Paul B. Hoeber, 1916. Pp. 179. (Price, $2.50.)

As the authors announce in their preface to this book, they have attempted to outline briefly the anatomy and physiology of the cerebellum as a basis for that neurological knowledge with which the surgeon must be equipped in order to cope with the problem of cerebellar diagnosis. It may be said that they have been successful in their attempt, and the result is a useful book of reference to surgeons who are engaged in work of this nature and indeed to the general practitioner. The majority of the cases of cerebellar abscesses are of otitic origin and come within the province of the specialist with regard to diagnosis and treatment; consequently, a work dealing with cerebellar abscess is timely. The authors present the subject clearly, the illustrations sufficiently illuminate the text, and the work should prove useful and instructive.

Interclinical Notes

Dr. I. M. Rubinow discusses Health Insurance in the *Survey* for July 15th; he talks about the "enthusiastic reception" with which plans have been greeted. Workmen may have shown this kind of excitement, but it has been conspicuously absent among physicians in general practice. The doctors who have taken up the question seriously are those on salary from industrial plants, whose problems are quite different from those of the regular practitioner. The fees now in vogue have been established, as prices used to be elsewhere, by the law of supply and demand, minus any chance of control by a "trust."

* * *

To manufacture smokeless powder, the only kind used in warfare, alcohol is required. P. Lincoln Mitchell discusses in *Leslie's* for July 13th the mental attitude of congressmen who are ardent for preparedness, but equally enthusiastic for prohibition. The only places where we could get large quantities of alcohol in a hurry are the distilleries. They could furnish enough for the daily manufacture of about eight million pounds of smokeless powder. Captain Mitchell states that this quantity is far below what is being exploded in the present war, and reminds us that alcohol would also be needed for industrial purposes and in medicine, and, furthermore, that it is extremely volatile. The question demands, as he says, the deepest study and most careful consideration.

* * *

Paul J. Banker writes an amusing article on Comma Hounds in *Commerce and Finance* for July 12th; it discusses people who are severe critics of slips in English, especially of misplaced or missing commas. The trouble with such people is that they fall foul of idiomatic English. They object to such phrases as "than whom," which do not bear analysis, but cannot be replaced.

* * *

Commerce and Finance for July 5th has something to say concerning disease. Paul J. Banker writes on the cure of cancer and on a new use for radium, viz., its offer as security for a loan. Reposing in three tubes, 105 mgm. of radium are now in the vault of a Chicago bank, hypothecated for $250,000. The article on The Problem of Price Maintenance has nothing to do with the editor's income from the periodical. We presume that Mr. Price is aware of the venerable age of the polysyllabic contribution he prints under the caption, A Cruel Criticism, which we have often seen before, including the slip in French, *double entendre* for *double entente*.

Official News

United States Public Health Service:

Official list of changes in the stations and duties of commissioned and other officers of the United States Public Health Service for the seven days ending July 26, 1916:

BOGGESS, JOHN S., Surgeon. Relieved at San Francisco, Cal., and take temporary charge of the Service at Seattle, Wash., effective August 1, 1916.

COLLINS, G. L., Surgeon. Directed to proceed to Milwaukee and other points in the State of Wisconsin for studies of the visual condition of female workers.

COX, O. H., Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

CUMMING, H. S., Surgeon. Directed to proceed to Philadelphia, Pa., relative to repairs to steamer *Murray*.

FOSTER, M. H., Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

FRICKS, L. D., Surgeon. Granted one week's leave of absence en route to Washington, D. C.

GLOVER, M. W., Surgeon. Granted one month's leave of absence from July 20, 1916, on account of sickness.

HEATON, W. D., Assistant Surgeon. Directed to report to the commanding officer of the Coast Guard cutter *Seminole*.

HERRING, R. A., Passed Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

HETTERICK, R. H., Passed Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

IVEY, R. R., Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

KALLOCH, P. C., Senior Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

LAVINDER, C. H., Surgeon. Directed to report to Washington for conference relative to the outbreak of poliomyelitis.

LLOYD, B. J., Surgeon. Granted five days' leave of absence from July 21, 1916.

MURRAY, VANCE B., Assistant Surgeon. Continued on duty at the Marine Hospital, San Francisco, Cal.

OAKLEY, J. H., Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

PARCHER, GEORGE, Passed Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

PETTUS, W. J., Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

ROBINSON, D. E., Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

SAFFORD, M. V., Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

SCHERESCHEWSKY, J. W., Surgeon. Directed to proceed to Madison and other points in the State of Wisconsin, to supervise studies of female workers now being conducted in that State.

SCHWARTZ, LOUIS, Passed Assistant Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

SMITH, H. F., Assistant Surgeon. Directed to proceed to New York for duty in the investigation and suppression of poliomyelitis.

SMITH, L. H., Assistant Surgeon. Directed to report to the commanding officer of the Coast Guard cutter *Onondaga*.

STEWART, P. M., Assistant Surgeon. Directed to proceed to New York for duty in the investigation and suppression of poliomyelitis.

STONER, J. B., Surgeon. Directed to proceed to New York for duty in the prevention of the interstate spread of poliomyelitis.

THOMPSON, L. R., Passed Assistant Surgeon. Directed to proceed to New York for duty in the investigation and suppression of poliomyelitis.

WELDON, L. O., Assistant Surgeon. Granted three weeks' leave of absence from August 1, 1916.

Appointments.

Dr. Vance Butler Murray, Dr. Lendon Howard Smith, Dr. William Daniel Heaton, and Dr. Robert Robbins Ivey appointed and commissioned as Assistant Surgeons from date of oath, July 14, 1916.

Boards Convened.

Boards of medical officers convened for the physical examination of members of the Coast Guard for promotion as follows:

Bureau, 3 "B" Street, S. E., Washington, D. C., July 31, 1916. Detail for the board: Assistant Surgeon-General W. G. Stimpson, chairman; Passed Assistant Surgeon W. F. Draper, recorder.

Marine Hospital, Detroit, Mich., July 24, 1916. Detail for the board: Senior Surgeon H. W. Austin, chairman; Surgeon H. W. Wickes, recorder.

Marine Hospital, Stapleton, N. Y., July 24, 1916. Detail for the board: Senior Surgeon George W. Stoner, chairman; Surgeon A. D. Foster, recorder.

Marine Hospital, Baltimore, Md., July 24, 1916. Detail for the board: Surgeon J. A. Nydegger, chairman; surgeon C. W. Vogel, recorder.

610 American National Insurance Building, Galveston, Tex., July 24, 1916. Detail for the board: Surgeon L. P. H. Bahrenburg, chairman; Surgeon R. L. Wilson, recorder.

Marine Hospital, Mobile, Ala., July 24, 1916. Detail for the board: Surgeon John T. Burkhalter, chairman; Acting Assistant Surgeon W. T. Deaver, recorder.

Marine Hospital, Port Townsend, Wash., July 24, 1916. Detail for the board: Passed Assistant Surgeon B. H. Earle, chairman; Acting Assistant Surgeon P. I. Carter, recorder.

Marine Hospital, Chelsea, Mass., July 24, 1916. Detail for the board: Passed Assistant Surgeon W. M. Bryan, chairman; Passed Asistant Surgeon R. A. Kearny, recorder.

Births, Marriages, and Deaths

Married.

BANCROFT-CROUSE.—In Philadelphia, Pa., on Thursday, May 18th, Dr. J. W. Bancroft and Miss Mary Catherine Crouse.

MOLEEN-CONWAY.—In Denver, Col., on Thursday, July 20th, Dr. George Arnold Moleen and Mrs. Mary L. Conway.

Died.

ASHFORD.—In Portland, Ore., on Wednesday, July 12th, Dr. J. W. Ashford.

HALL.—In Conshohocken, Pa., on Tuesday, July 25th, Dr. William M. Hall, aged fifty-six years.

HEADY.—In Glendale, Ohio, on Monday, July 24th, Dr. James F. Heady, aged sixty-four years.

JENNINGS.—In Hot Springs, S. D., on Tuesday, July 11th, Dr. Rudolphus D. Jennings, aged sixty-three years.

KING.—In New London, Conn., on Friday, July 14th, Dr. John A. King, aged forty-four years.

LANGLEY.—In Angelica, N. Y., on Saturday, July 22nd, Dr. William Langley, aged forty years.

LEGER.—In Bayland, Texas, on Wednesday, July 12th, Dr. A. E. Leger, aged seventy-four years.

LONGINO.—In Fairburn, Ga., on Thursday, July 20th, Dr. John T. Longino, aged forty-seven years.

LOVETT.—In Norman Park, Ga., on Friday, July 21st, Dr. William Lovett, aged thirty-four years.

MCKELVY.—In Denver, Col., on Thursday, July 13th, Dr. William McKelvy, aged sixty-two years.

MCKELVEEN.—In Chariton, Iowa, on Sunday, July 16th, Dr. John A. McKelveen, aged eighty years.

MARSTELLER.—In Washington, D. C., on Sunday, July 23rd, Dr. Emlyn H. Marsteller, aged sixty-five years.

MURRAY.—In Atlanta, Ga., on Thursday, July 20th, Dr. Price E. Murray, aged sixty-three years.

OBERG.—In New Bedford, Mass,. on Monday, July 17th, Dr. Charles H. Oberg, of Hot Springs, Ark., aged thirty-seven years.

PAXSON.—In Christiana, Pa., on Sunday, July 23rd, Dr. Oliver H. Paxson, aged sixty-two years.

THE STORY OF DEMENTIA PRÆCOX.*

BY FRANCIS X. DERCUM, M. D.

Philadelphia.

The story of dementia præcox begins before the foundation of the organism is laid. The building material is imperfect, poor in quality, vitiated, so that the resulting structure crumbles and gives way under its own strains. All observers are agreed as to the large proportion of hereditary factors in dementia præcox. These are variously estimated at from fifty-two per cent. (Schott) to ninety per cent. (Zablocka). The wide variation in the percentages of different observers is probably due to differences of view as to what should be included, first, in the general term of hereditary factors, and, secondly, as to what affections should be included in the general conception of dementia præcox. Kraepelin at one time found hereditary predisposition to mental diseases in seventy per cent. of his cases, though he thinks that this may possibly have been too high. He states that when the inquiry was limited to the direct heredity, i. e., to the occurrence of mental disease, suicide, or severe brain affections in the parents, it yielded 33.7 per cent., which he again regards as too low. No matter how we approach the subject, however, the facts justify the general conclusion as to the relative frequency of neuropathic family histories in dementia præcox. In such family histories should be noted not only crass instances of mental disease, but also the occurrence of eccentric or unusual personalities, criminals, prostitutes, tramps, vagabonds, misfits, and failures generally. We cannot but be impressed by the wide variations in the hereditary findings in dementia præcox when compared with the relatively limited and definite character of such findings in manic depressive insanity.

It is undoubtedly significant that every now and then dementia præcox occurs in a number of individuals in the same family. Kraepelin states that he knows a large number of such instances. Personally I have knowledge of one family in which no fewer than five individuals acquired this disease. Dementia præcox is only infrequently transmitted from parent to child, as the great mass of cases develop before parenthood is established. This statement must, of course, be modified in so far as we include the paranoid—that is, the older cases—under the general caption of dementia præcox. It is true, however, of the great mass of hebephrenics and catatonics. Further, not only are instances of dementia præcox met with in the same family, but other affections as well, such as epilepsy and hysteria, and at times also, though infrequently, manic depressive insanity.

What is it that is transmitted to an organism from a diseased parent stock? In what way is the germ plasm affected? While we are as yet unable to give a definite answer to these questions, the fact of the transmission of impairment or defect cannot itself be questioned. The French have a very happy expression to convey this idea, they speak of *tares héréditaires,* the hereditary blemishes; while the Germans employ the very expressive term, *hereditäre Belastungen,* the hereditary burdens. Rüdin, from studies made of Kraepelin's material, comes to the conclusion that dementia præcox is probably transmitted in accordance with the Mendelian law and appears as a recessive quality. In favor of this view he regards the marked predominance of the collateral and discontinuous inheritance over the direct inheritance, the increase of dementia præcox resulting from inbreeding, and the numerical relation of those attacked to those remaining normal. He found in the families which he studied also other affections, namely, manic depressive insanity and eccentric personalities, and further that it was not at all infrequent for manic depressive parents to produce children with dementia præcox, while the reverse—namely, manic depressive children from dementia præcox parents—belonged to the rare exception. Granting the possible transmission of dementia præcox in accordance with the Mendelian law, it is also evident that other factors which directly and grossly affect the vitality and development of the organism variously play a role. For instance, Rüdin noted that late born or last born children suffered more frequently from dementia præcox than others; again, that immediately preceding or following the birth of a præcox patient there was frequently a history of miscarriage, premature birth, or stillbirth. Of equal significance are the physical and psychic stigmata of deviation and arrest that are found in individuals who acquire dementia præcox. Saiz states that the frequency of the occurrence of the physical stigmata is seventy-five per cent. Among the latter are physical feebleness, retardation of growth, a too prolonged juve-

*Read before the Philadelphia Psychiatric Society, May 12, 1916.

nile appearance, malformations of the skull, deep and narrow palate, persistence of the intermaxillary bone, abnormalities of the ears, fingers, or toes, imperfections and anomalies of the teeth, and allied peculiarities.

Facts such as the foregoing would suggest that in addition to the special *tare* or blemish, the *Belastung* or burden—which the germ plasm transmits in accordance with Mendel's law—the germ plasm may also suffer from impairments that affect its general morphological and biological character and profoundly alter and lower its possibilities of growth and development. Among causes which may thus grossly impair the germ plasm, we have reason to believe, are infections and intoxications affecting the parent. Pilcz, Klutscheff, and others have published suggestive statistics as to the frequency of syphilis in the parents. That syphilis may play a role is extremely probable on other grounds. The fact that the Wassermann reaction is found in a not inconsiderable proportion of dementia præcox cases, e. g., by Bahr in 32.1 per cent., is of extreme significance. Such findings do not mean that the patients are suffering from a disease of the nervous system due to inherited syphilis, but that the organism as a whole has been hampered, made deviate and degenerate in its development by the presence of the spirochete and its toxins; i. e., that the evolution of the organism as a whole—and included in this the development of its glands of internal secretion—has been so inhibited and altered that at a given point in its life the organism breaks down by reason of an abnormal and toxic metabolism.

The clinical evidences of inherited syphilis are absent in the great mass of dementia præcox cases, and it is not necessary that the Wassermann or other tests should yield a positive result; it is sufficient that the infection has damaged the germ plasm of the parent. Again, that alcohol likewise damages the germ plasm hardly admits of doubt. Diem, Fuhrmann, Rüdin, Wolfsohn, and others have published studies, alike suggestive and significant, on the alcoholism of parents in dementia præcox. Whether other poisons and intoxications play a role in bringing about damage to the germ plasm, we are obviously unable to say, but such action is neither impossible nor improbable. In any event, however, it must be vastly less important than the action of syphilis or of alcohol.

To recapitulate: It seems justifiable to assume, first, that the germ plasm in dementia præcox may be laden with a direct tendency to the development of dementia præcox, a tendency which may possibly, as Rüdin believes, be transmitted as a recessive quality in conformity with Mendelian principles: secondly, the germ plasm may suffer from a gross impairment the result of syphilis, alcohol, or more rarely of other infections or intoxications.

The first cause could be operative without the second; both causes could be operative—and probably frequently are operative—together. Whether the second cause could be operative alone, is a question at first sight difficult to answer. To me the answer seems to depend upon whether we are to regard dementia præcox as a specific clinical entity —such as manic-depressive insanity—or whether we are to regard it as a group of mental affections all of which present the one common factor of endogenous deterioration. If we take the latter view, we may unhesitatingly answer the question in the affirmative.

I shall not pause to discuss the possible role in etiology of infections—i. e., the exanthemata—and traumata, affecting the individual. Certain it is that our clinical histories do not justify the assignment to them of a causal value, or at most only remotely or in rare instances, perhaps, the role of exciting causes. Whether infections in early life may so affect the glands of internal secretion as to lead later to the development of dementia præcox, is a possibility, but has little evidence upon which to rest.

The conception of dementia præcox which I have thus far endeavored to outline, is that of an organism which has its beginnings in a germ plasm defective and abnormal, and whose subsequent development is necessarily imperfect and deviate. It means that the organism as a whole is involved. This also must be inferred from the presence of such evidences of morphological deviation as are visible to clinical observation; these merely imply that other and fundamental deviations are present in the organism throughout. Such an organism must present not only abnormalities of its structure, but also abnormalities of function and especially of its metabolism. Various facts point to anomalies of the internal secretions. For instance, it is not infrequently noted that the thyroid gland varies in size from the normal; frequently it is unusually small, though occasionally enlarged. Autopsies have shown (Dercum and Ellis) that it is frequently only half the normal weight, while the adrenals are frequently double the normal weight. The role that other glands such as the thymus may play in dementia præcox, has been pointed out by Sajous. Indeed it is extremely probable that the entire chain of ductless glands may participate. Clinically our attention is strongly attracted to the sex glands. There are the anomalies of menstruation, the delayed and imperfect establishment of puberty on the one hand, or of sexual precocity on the other. Again, there is the history of sexual excesses, sexual vagaries, and perversions. A relation to the sex glands is further indicated by the accentuation of symptoms often observed during a menstrual epoch and by the fact that dementia præcox now and then has its incidence in a pregnancy or in repeated pregnancies, or in a miscarriage, as though sex gland exhaustion played a role. Tsisch, Lomer, and Kraepelin have all assigned importance to the sex glands. Lomer, particularly, indicated a disturbance of the internal secretion of the latter, but it remained for Fauser to throw an especially illuminating light upon the subject. It would appear from Fauser's investigations that in dementia præcox unchanged sex gland protein—an abnormal internal secretion of the sex gland—enters the blood and that in the subsequent breaking up of this protein, substances—defensive ferments—are formed which are poisonous to cortical tissue and which bring about the destruction, the lysis of the latter. Fauser's results, as I have pointed out in a previous paper, have been confirmed by a large

number of other investigators. Whatever the future may reveal, there is no escape from the conclusion that in dementia præcox there is a deranged metabolism, an autotoxic state, in which abnormalities of the internal secretions play a dominant role; that the internal secretions of the sex glands are especially involved is extremely probable.

When we turn our attention to the mental symptoms presented in dementia præcox cases, we are impressed by the fact that in the beginning the symptoms are not those of dementia, but those of confusion, just such symptoms as we should expect in a toxic state. The onset of symptoms is gradual, usually bearing the character of a confusion, sometimes with elements of systematization and accompanied by exhaustion. The elements of confusion, dissociation, hallucinations, illusions, unsystematized or feebly systematized and fragmentary delusions, are all present in a more or less dominant degree. Years ago, Régis, Christian, Anglade, Macpherson, Sérieux, Trepsat, Dide, and others frankly treated this mental state as a confusion, and this is an interpretation which I have myself emphasized. A word that Kraepelin frequently employs in describing it is *Zerfahrenheit,* which can only be rendered as confusion or dissociation. Admitting freely the fact of confusion, however, it soon becomes evident that other elements are present which demand consideration. First among these is the element of exhaustion. A recognition of this factor is of the utmost importance. In it I believe lies in a large measure the explanation of some of the symptoms which seem special or peculiar to dementia præcox. There is in dementia præcox, as in psychasthenia and in hysteria, a diminution in the activity of the field of consciousness. Janet has expressed this idea by the words, *abaissement du niveau mental* (lowering of the mental level). I have myself in various papers used the expression "reduction of the field of consciousness" to convey the same idea. Weygandt, in discussing the psychology of the mental feebleness in dementia præcox, terms the end process of the disease an "apperceptive dementia." I do not think that much is gained by the use of this term. According to Wundt, apperception is the special process by which any psychic content is brought to clear apprehension. Into such a process many factors must enter—an act of will, the multiple qualities of the object or idea, the sensations, emotions, and, as a corollary, the impulses to which these necessarily give rise. Evidently an apperception embraces many if not all of the factors of psychic activity, and to speak of an apperceptive dementia conveys little more than to speak of dementia as a whole. Further, Weygandt, it is to be noted, applies the term only to the end process of dementia præcox. Dementia præcox, as we all know and as has already been emphasized in this paper, is not a dementia in the beginning, but only in the more advanced stages of the disease. The term, apperceptive dementia, is not, therefore, as Jung would have us believe, the equivalent of Janet's term, "depression of the mental level," and if we strive to modify it by changing it into "apperceptive weakness" little is gained for the reasons already indicated. Janet's term, which forms the keystone of his conception of psychasthenia, is applied to the dynamic state of the mind. Psychasthenia is essentially a state of psychic adynamia. This is exactly the idea that is conveyed by the term "depression of the mental level." It is a condition of the mind in which the force, the intensity of its processes is lowered. The mind in such a state is like a fire which, instead of burning brightly, is reduced to embers it may be, barely glowing. It is not a state, however, which necessarily implies disintegration, deterioration, or dementia.

The existence of such a diminished activity of the field of consciousness can, I think, be admitted without hesitation. It is essentially a state in which the intensity, the vigor of the metabolic processes of the cortex are lessened, just such a state as we have reason to believe exists in psychasthenia. When we fully appreciate this fact, it illuminates much in the symptomatology of dementia præcox that seems obscure. Let us briefly consider some of the symptoms. The slowness of speech and poverty of thought, which eventuate in mutism, in catatonia, in stupor, find their measure of explanation in an adynamic state. This is also true of fixation of position, stereotypy, automatism, perseveration, verbigeration. Here the psychic current, which in the normal mind is like a river broad and deep and easily flowing, has been reduced to a shallow, a narrow, and a monotonously trickling stream. Continuous or interrupted, it is the only thing that remains in the field of consciousness. Jung and others have thought that its monotony, its sameness, is due to the fact that the entrance of other associations into the stream is inhibited or blocked; but surely dams, obstructions, are not necessary when the beds of the tributary streams are dry, for we must remember that the cortex is adynamic as a whole. Again, it would appear that the adynamic state of the cortex does not involve the latter equally or uniformly and, here and there, now and anon, tributary currents join what is left of the main stream, but they do so irregularly, at unusual points, and at variance with the orderly sequence of normal psychic processes. We find that instead of normal associations, mere sound associations, associations of coarse resemblances, and of mere contiguity are produced.

Again, it may happen that the field of consciousness is more greatly reduced dynamically than the cortex as a whole or than other portions of the latter. Now, it is probable that under normal conditions, the activity of the psychic field is so great that it diffuses to and beyond the boundaries of consciousness, but if the activity of the psychic field is relatively diminished, it results dynamically that the direction of the diffusion is reversed, and that other activities now flow into this less resistant field. These activities probably consist of complexes—of groups of associated ideas—of greater relative dynamic power. Negativism probably finds its explanation in the fact that every impulse or feeling is represented in the psychic makeup, not only by a positive complex, but also by its exact opposite; indeed, it is probable that the positive complex owes its existence to its differentiation from the general psychic material, which thus becomes its negative. Now it would seem that in the lowered, adynamic

state of the field of consciousness the positive complex cannot find expression; of necessity, its opposite, being dynamically stronger, flows into the field and finds expression. The symptom to which Bleuler has given the name, ambivalence, and which consists in the tendency of the patient to give expression equally to opposing impulses, has, it would seem, a similar explanation and need not detain us. It may be pointed out, however, that ambivalence is first cousin to the symptom of indecision of the typical psychasthenic. Again, the aboulia of catatonia also finds a ready explanation in the adynamic mental state. Further, the lack of inhibition, impulsivity, clownism, mannerisms, special gestures are also rooted in the same condition. The particular picture presented by a given case at a given time is obviously linked with the nature and character of the thought or psychic process that is persisting in the narrowed field of consciousness. It is not surprising, for instance, that a tailor should make recurring movements of sewing or a woman of washing or wiping. Our Freudian friends, however, see in such phenomena the persistence of repressed complexes.

The hallucinations present in dementia præcox are due apparently to the toxic irritation of sensory areas of the cortex. The excitation resulting breaks in an unrelated manner into the field of consciousness, and the impression produced on the mind of the patient is that of a sensation of extraneous origin. No wonder that the patient refers the noises and the voices to the external world. In such a case a separate portion of the personality addresses itself to the main body of consciousness. Very frequently, indeed, almost always, visceral hallucinations and often sexual hallucinations are also present. The delusions—and I am speaking now mainly of the hebephrenic and catatonic forms—are often feebly held, commonly disconnected and disordered, and at most but poorly systematized. What a fertile field, what a wealth of repressed sexual complexes, they have yielded to the psychanalyst I need not say. That the portion of the cortex irritated by the toxin may be other than a sensory area need hardly be pointed out. In this way long buried associations—associations which have no relation to the subject matter of the field of consciousness—may break in just as do hallucinations. That such associations are regarded as strangers by the psyche of the patient can also be readily understood. At other times, owing to the low dynamic tension of the field of consciousness, associations long dormant may diffuse into the field, may become incorporated with the stream of thought, and may greatly modify the clinical picture presented; and that this enters into the explanation of such symptoms as impulsivity, clownism, special gestures, and the like is extremely probable.

Bleuler, in his article on dementia præcox in Aschaffenburg's *Handbuch der Psychiatrie,* makes a most elaborate subdivision of the mental symptoms, a subdivision which I believe, instead of illuminating the subject tends to add to its obscurity. I shall not, for instance, take up the subject of autism and autistic thinking. To me it seems quite natural that a patient in a condition of psychic adynamia and suffering with numerous visceral or, better, cenesthetic hallucinations, should be taken up with his own world of self, with its persecutions or its expansions; which last our Freudians translate into wish fulfilments. I cannot understand, however, why this autism should be given a sexual character as is done by the psychanalyists; Freud, for instance, employs in its stead the term autoerotism; but it is difficult for that matter to understand the psychanalyst's attitude at all, especially when as Bleuler says the only treatment for dementia præcox is the psychic treatment. Inasmuch, he tells us, as the symptomatology of the disease is dominated by the complexes, and as these enable us to penetrate into the psyche of the patient, we should expect to be able in this manner to influence them. To talk of psychanalysis as a treatment for a patient with the earmarks of defective development, a positive Wassermann, a toxic metabolism, defensive ferments, and what not, is to my mind very much like attempting to treat a broken leg or a typhoid fever by the same method.

Thus far we have considered the toxemia and the psychasthenic or psychadynamic background of the disease. A word is still necessary to complete the picture—outline picture only though it is—of the symptoms. The disease is essentially one of adolescence, one of the developing period of life, and is usually gradual in its course. Both factors permit for a longer or shorter period, the preservation in many cases of a relatively high degree of lucidity. This lucidity becomes impaired in proportion as disturbed and hallucinatory or stuporous states are established. During this relative lucidity perception is good, illusions are infrequent and often altogether absent. That orientation under these circumstances should be well preserved is exactly what we should expect. For a like reason, memory is good, not only for the period preceding the onset, but for a long time thereafter. Like the lucidity and orientation it may show impairment or loss only during and for the periods of disturbed and stuporous states. In the terminal stage the memory suffers along with the other faculties.

The story of dementia præcox begins, as we have seen, with an impaired germ plasm. It deals with an organism defective and deviate in its development, a quality which involves the nervous system as well as the other structures. In the course of its development the organism becomes toxic through a metabolic breakdown and as a result of the mere strain of living. The cortex, already feeble and with diminished resistance, becomes a prey alike to exhaustion and intoxication, and the subsequent course is one of deterioration, and the final chapter one of dementia.

That under circumstances like these the clinical picture should vary greatly is not surprising. How much individual cases differ from each other we all know, and the tendency to separate out from the great mass of cases special forms is well illustrated in the last, the eighth edition of Kraepelin's *Psychiatrie,* in which no less than eight forms are differentiated. Careful clinical studies will greatly increase our knowledge of the details of the course and the final outcome of the different symptom

groups, but I venture the prediction that the original classification into the hebephrenic, catatonic, and paranoid forms as presented in Kraepelin's original generalizations, modified it may be by subdivisions, is the one which will survive.

To my mind also, Kraepelin has gone too far in embracing under the generalization of dementia præcox the hallucinatory paranoid states of the adult. Purposes of study and of clinical distinction are best served by limiting the conception of dementia præcox to the endogenous deteriorations of adolescence. Besides—a fact which Kraepelin himself well recognized—the paranoid dementias of youth and beginning of adult life present striking differences both in the less definite, less fixed character of the delusions and by a much more rapid evolution and course. Indeed Kraepelin early differentiated them as a separate form, speaking of them as paranoid dementia of the *first* form. Other writers, among them Mendel, Schüle, and Siemerling, have done the same thing, employing the expression paranoia acuta. The French likewise have given it a special name. Magnan calls it the *délire d'emblée des dégénérés* because of its rapid evolution, while other French writers have called it *délires systématisés aigus*. It is an insanity of the adolescent period and seems to form a natural group with hebephrenia and catatonia.

The paranoid dementia of the adult is vastly slower of evolution, is of lifelong duration, and presents a degree of fixation, systematization, and lucidity which is in crass contrast with the juvenile form. For the adult form I much prefer the more distinctive term, hallucinatory paranoia. In his seventh edition Kraepelin describes it as the *second* form of paranoid dementia; in his eighth edition he has abandoned the term paranoid altogether as applied to this group of cases and has substituted the word paraphrenia. To my mind this does not improve matters, for the words paraphrenia and paranoia mean essentially the same thing. Finally Kraepelin does violence—and I say this with all due deference—in separating so widely the lucid paranoia of the adults, i. e., the paranoia simplex of Ziehen, the paranoia chronica of Siemerling, the *Verrücktheit* of Westphal and Sander, the *délires systématisés des dégénérés* of Magnan, from the other paranoid forms.[1]

In conclusion, I wish to speak of but one other point. Bleuler has devised and proposed as a substitute for the name, dementia præcox, the word schizophrenia, an expression which means cleft or divided mind. That the mind in dementia præcox reveals dissociations, fissurations, cleavages, no one will attempt to deny, but this is a quality which it shares with many other forms of mental disease and especially with those far removed states, hysteria and hypnosis. The term, schizophrenia, is not distinctive and I trust it will not survive. Perhaps in the future some term will be invented which will convey the idea of endogenous deterioration in adolescence, but until then we had best adhere to the name, dementia præcox.

1719 Walnut Street.

[1]The space assigned to me forbids an extended discussion of this question here on my part.

CONGENITAL SYPHILIS.*

The Prognosis and Modern Treatment,

By Fred Wise, M. D.,
New York.
Instructor, Dermatology and Syphilology, Columbia University; Chief of Clinic, Dermatological Dispensaries, Mt. Sinai and Beth Israel Hospitals.

At the very beginning I must ask my readers to resign themselves to the perusal of a paper, the substance of which is based chiefly upon and derived mainly from the investigations of those whose opportunities have enabled them to care for many cases of congenital syphilis. These investigators have gained their knowledge and have formulated their data in their capacity of medical officers in large institutions, in this country and abroad. They were enabled not only to administer antiluetic treatment to their congenitally syphilitic charges, but also to follow up their cases and to observe the effect which the treatment had upon the clinical and serological manifestations of their patients. As to my own knowledge of the subject, what little I know has been gained, in great part, by reading the current literature. Though it is true that syphilitic patients form a large proportion of the clinical material which I encounter in my daily work, it is equally true that the congenital type of the disease represents only a very small fraction thereof.

It is the prevalent opinion that in congenital syphilis, the effects obtained by modern methods of treatment are not as productive of good results as is the case in acquired syphilis. This view has been fortified, in recent years, by data based upon microscopic and serological investigations in congenitally luetic individuals. According to E. Welde (1), however, recent workers in this field have shown a strong tendency toward a more optimistic attitude. In former years, for example, the prognosis was considered good only in breast fed infants. Nowadays, it is admitted that artificially fed infants may thrive and get well, other factors being favorable (Finkelstein).

Congenital syphilis has shared with acquired syphilis the benefits derived from the recent discoveries in the bacteriology, serology, and treatment of the disease. The good results obtained today in the treatment of congenital syphilis, are due partly to these discoveries, but also to the more accurate knowledge of the principles of infant feeding and the general care of the luetic infant.

TREATMENT.

The signs and symptoms by means of which congenital syphilis may be recognized have frequently been described. Having arrived at the diagnosis, the next step is immediately to combat the spirochetal septicemia, with the same energy and expedition as we now know is essential in cases of recently acquired syphilis in older patients.

Beside the specific treatment, however, we must also bear in mind the necessity of directing our efforts toward alleviating the nutritive and other functional disturbances which the infant may present, and, in the majority of cases, does present. When-

*Read before the Regular Meeting of the Bronx Medical Society, Wednesday, March 15, 1916.

ever possible, the mother should nurse her child. Should this be not feasible, for one reason or another, the next step (according to most European authors) is to employ a wetnurse who is known to suffer from syphilis. This nurse is to be apprised of the fact that she is to suckle a syphilitic child. In cases where the mother is obviously and actively syphilitic, but has given birth to a child who is apparently in good health, breast feeding by the mother is, of course, not to be thought of. But if the mother has received adequate and thorough antisyphilitic treatment before and during the period of gestation, and therefore is the subject of so called latent syphilis, she may be permitted to suckle her newborn child. Should this again be impracticable, a wetnurse in an analogous stage of syphilis may be substituted (F. Hell).

With reference to the familiar phenomenon manifested by an actively syphilitic woman giving birth to an apparently healthy child, attention should be directed to the well established fact that a negative Wassermann reaction in a newborn child does not exclude the presence of syphilis, and that weeks, or even months may elapse before it presents symptoms of the disease, or before the Wassermann test becomes positive. In all cases, therefore, where the mother is known to suffer or to have suffered from syphilis, we must keep a watchful eye on her apparently healthy offspring, we must make frequent and systematic examinations of the patient's skin and mucous membranes, and blood tests must be performed at certain intervals over a period of several months.

Lues hereditaria tarda is considered by most authors to be a manifestation of a recurrence or récidive of the disease which had existed in infancy and in which the clinical symptoms disappeared rapidly, with or without adequate treatment. True cases of lues hereditaria tarda can be proved to be such only if the child had been under constant clinical and serological surveillance during its entire lifetime, had had no clinical or serological manifestations of syphilis in infancy, but did present syphilitic lesions and a positive Wassermann test in later life (Welde). Kaposi, Neumann, Fournier, Heubner, and others denied the existence of a true syphilis tarda, but permitted the designation when referring to cases which manifested the first symptoms of congenital syphilis in later childhood years. Sprinz believes that the majority of cases designated as syphilis tarda by most authors, present the first symptoms of congenital disease between the twelfth year and puberty; and that cases of syphilis tarda do not occur after the third decade.

In former years it was attempted to treat infants indirectly through the milk of mothers, wetnurses, cows, goats, etc., which had been subjected to courses of mercurial medication. The same method has also been tried with salvarsan. Taege, Duhot, Neisser, Scholtz, Freund, and others administered salvarsan to the child, indirectly, through the mother's breast milk. Jesionek obtained fair results by giving the child milk from a goat, to which salvarsan had been administered intravenously. These results were, however, rather variable and inconstant. It was then attempted to administer salvarsan intramuscularly, but this was abandoned on account of local necroses. The technic was improved later, so that satisfactory results were obtained by Galewsky, Herxheimer, Schoenfeld, Ritter, Schreiber, and others. In spite of improvements in the technic, however, necroses still occurred. It was only with the advent of neosalvarsan that these objections were overcome. Neosalvarsan may be administered intravenously if there are prominent veins; if not, it may be given intramuscularly.

According to F. Hell, treatment is begun as soon as the diagnosis is certain. Due importance is placed upon general hygienic measures, especially breast feeding. Sublimate baths and calomel internally have been discarded, the former on the ground of inefficacy, the latter on account of gastrointestinal disturbances. Mercury is administered by inunction or by intragluteal injections. Inunctions are given daily, for six days, on the seventh day a bath, and in this way are continued from four to six weeks. Unguentum cinereum (0.3 to 0.5 gram daily) is gently rubbed on the arms, legs, chest, and back, on successive days; each rubbing takes from five to ten minutes. If sublimate injections are employed, they are given twice weekly, in doses of 0.003 to 0.005 gram (sublimate 1.0, sodium chloride 10.0, distilled water 100). They are well borne, even when the gluteal musculature is poorly developed (M. Scheer, 2). Salvarsan is never used, on account of danger of necrosis. After preliminary mercurial treatment, neosalvarsan is administered weekly, for four to six injections, in doses of 0.005 to 0.15 gram, dissolved in a little distilled water. It is given intravenously, in the temporal veins or intragluteally. (M. Scheer, 2.)

The treatment is controlled by the Wassermann test. It is much harder to make this negative and to keep it negative in congenital, than in acquired syphilis. After a few months, every case receives a second course, most receive a third, and a few a fourth. If this method of treatment is conscientiously carried out, the outlook for the syphilitic infant will be more hopeful than with previous methods of treatment.

In recent years Erich Mueller (3), of Berlin, has prolonged the period which he formerly thought sufficient for a course of treatment in children with congenital syphilis. Mueller now gives eight neosalvarsan injections, alternating them with intramuscular calomel injections. In children of two years or more, he administers a preliminary course of blue ointment inunctions, alternating with the calomel injections. He prolonged the length of time of each course of treatment, when he found it difficult to obtain a permanently negative Wassermann reaction from the older methods, in which, in many cases, a negative Wassermann was soon followed by a positive. The object was to destroy all spirochetes in the first one or two courses. The methods which he employed until recent years did not produce such an ideal result. It has often been emphasized how difficult it is to obtain a lasting negative reaction in infants. In Mueller's opinion, the significance of the Wassermann reaction in luetic infants has the same bearing on their malady as it has in acquired syphilis in adults. Congenital syphilis simply was

not treated adequately to produce the desired clinical and serological results. In nursing infants he employs a suspension of calomel in olive oil, intramuscularly. He did not find the bichloride efficacious, although the clinical signs disappeared. Oral administrations had been abandoned on account of gastrointestinal disturbances.

According to Mueller's plan, a single course of treatment (*Kur*) consists of either twelve calomel injections, combined with eight neosalvarsan injections, or of a six weeks' inunction course, also combined with eight neosalvarsan injections. Both courses extend over a period of about three months. After such a three months' course there is a rest of three months, then a second, similar course is given, followed by a third course after another rest of three months.

After the second year calomel injections and inunctions of mercury are alternated. In nursing infants, it is best to avoid inunctions, on account of delicacy of the skin and the small areas of skin available for the rubbings. He employs doses of 0.001 grams of calomel and 0.015 grains of neosalvarsan per kgm. of body weight. A child of 4.3 kgm. receives 0.004 gram of calomel and 0.07 gram of neosalvarsan. The injections are given in the outer and upper quardrant of the nates. Neosalvarsan, in suckling infants, is given intravenously into the veins of the scalp, those of the leg, or, best of all, into the longitudinal sinus of the scalp. Only in exceptional cases do nursing infants receive neosalvarsan intramuscularly. In older children it is usually given into the muscles, as the veins are more difficult to reach. Calomel is used in from three to five per cent. emulsion in olive oil. The dose of blue ointment is as follows: For ten kgm. body weight he gives one gram. A child of twenty kgm. weight gets six rubbings a week, with a total of two grams of mercury. The ointment is rubbed in for twenty minutes.

Each course begins with mercurial medication, not with neosalvarsan, to avoid the possible toxic symptoms due to too rapid destruction of the spirochetes. Each course is ended with four successive calomel injections, or two weeks of mercury inunctions. No ill effects upon the kidneys have been noted, but Mueller advises that the urine be frequently examined. The calomel injections are well borne, by breast fed infants especially. They are not more painful than bichloride injections. In older children, infiltrations and small abscesses are more frequent; the treatment is then changed to inunctions. One week of inunctions takes the place of two calomel injections.

The number of separate courses is determined by the results of the serological blood tests. The Wassermann test is made just before each course, and eight to ten days after each course. The result obtained before the course determines the amount of subsequent treatment. After the first negative Wassermann reaction, every child receives two more courses, even if there is no reversion to the positive reaction. If the reaction becomes positive, then the number of courses is proportionately increased. In the average case, the child receives from three to five courses. If the reaction is still positive, Mueller persists in the treatment until it becomes negative.

The entire period of treatment requires one and a quarter to one and a half year, consisting of three courses, each about three months in length. After the final three months' course he administers a provocative neosalvarsan injection. The Wassermann test is taken on the second and ninth day after. Upon this test depends the question of further treatment. In cases showing mental deficiency the spinal fluid is examined. Mueller never obtained a positive spinal Wassermann in children whose blood Wassermann was negative.

Among breast fed infants, sudden death sometimes took place. This occurred usually in infants who obviously were very ill and who appeared to go into sudden collapse. Such deaths were reported as often in the first week of treatment, when mercury alone was used, as in the subsequent weeks when neosalvarsan was used. Hence it is assumed that the medication itself is not the cause of death, but rather that it is due to the toxins from the spirochetes. Once the initial course has been successfully completed, the children usually thrive without trouble. Intercurrent affections, such as grippe, are dangerous to the younger infants. It was noticed that children displaying mental defects during the early period of treatment did not improve in those symptoms after subsequent courses; in fact, some of them become worse. Mental defects, therefore, are difficult to treat. Mueller encountered children who exhibited only slight mental defects and no other symptoms of the disease, in whom the diagnosis was made on the evidence of a positive Wassermann reaction alone.

In his concluding remarks, Mueller states that in his experience, congenital syphilis is curable, provided that the treatment is intensive and sufficiently prolonged.

Soldin and Lesser (4) made a study of a number of infants admitted to one of the Berlin hospitals for disturbances other than syphilis. None of these children had recognizable symptoms of early syphilis. Snuffles were not pronounced, very few skin rashes were seen, epitrochlear glands were hardly palpable, swellings of the spleen and liver were negligible. Many patients showed no syphilitic manifestations whatever. The Wassermann reactions, in most of these cases, were negative, although those of the mothers were invariably positive. An explanation of the negative Wassermann and the absence of the clinical symptoms in the infants is given as follows: During the intrauterine life of the child, immunizing substances from the syphilitic mother were transferred to the children, and these immunizing substances hindered the further transplantation of the spirochetes to the child. Even in the cases where the Wassermann reaction was positive in the infants, no clinical symptoms were observable. In conclusion, the authors state that the practical application of this study lies in the fact that, when there is the slightest suspicion of congenital syphilis, the physician ought not to be satisfied with an examination of the infant's blood alone, but should always order a serological examination of the mother (5).

Strathy and Campbell (6) report On the Results

of Treatment with Salvarsan in Late Congenital Syphilis. The writers treated with salvarsan eighteen cases, most of which exhibited bone lesions. Ordinarily, the injection was made into the median basilic or median cephalic vein, occasionally into the external jugular. At first the treatment was given once a month, but later it was repeated every one or two weeks. The blood serum was tested within forty-eight to seventy-two hours after the injection. No result was considered finally negative unless given by the blood taken within this period. The authors agree with McDonagh as to the provocative power of salvarsan. For each pound of body weight, they gave a dose of one c. c. of salvarsan solution of 0.6 gram in 300 c. c. and two c. c. of neosalvarsan solution of 0.9 gram in 150 c. c. of solution.

The effect upon the Wassermann reaction was not satisfactory, although comparable with that obtained with mercury. Gummata, periostitis, and ulcers disappeared rapidly. Interstitial keratitis healed more quickly than under the mixed treatment, and, therefore, with less scarring. The results were better than with mercury, about one half the cases being mercury resistant. Hereafter, they will use larger doses of salvarsan, even to the limit of tolerance, and repeat the dose at intervals of less than seven days. The Wassermann reaction became negative in only two cases, although all improved clinically. In their experience, they found that the younger the child, the more rapid the effect upon the Wassermann reaction (7).

In a recent publication, La Fetra (8) submits some interesting findings in congenital syphilis as it occurs in New York. He says, in part:

To give some idea of the clinical types of hereditary specific disease met with in children, I have gone through the records of the Bellevue Hospital Children's service for the past two and one half years. During all this time careful Wassermann tests have been made on all cases with suspicious physical signs or symptoms. In the period investigated there were 148 cases of syphilis admitted to the wards. Of these, three were cases of acquired syphilis, eighty-five were hereditary but under one year of age, and the remaining sixty were of the hereditary type and over one year. Of these sixty patients, there were ten that showed no symptoms nor physical signs at all characteristic of hereditary syphilis. One child of six years had no symptoms nor any abnormality whatever; she was sent into the hospital for treatment because she belonged to a syphilitic family and because on this account a Wassermann reaction had been taken and found strongly positive. . . . Of the sixty cases there were suspicions or equivocal signs in twenty-one. . . . In none of these cases were the signs, though suggestive, sufficiently characteristic, at the time of admission, to warrant a positive diagnosis. Twenty-nine of these sixty cases had signs that were characteristic of hereditary syphilis. . . . The most important lesson one derives from a consideration of the symptoms and signs found in cases of hereditary syphilis is the well worn conclusion that an early diagnosis, with its corollary of vigorous treatment, is of the highest possible value to the patient. As an aid to this early diagnosis, in doubtful cases, the Wassermann test, carefully made by a competent man, may be relied upon almost absolutely. It is exceedingly rare that the test fails to comport with the physical signs, and in such cases there is usually either delay in having the blood reach the laboratory, the serum becoming anticomplementary, or there is something wrong with antigens used in the test. The more frequently the Wassermann test is employed—especially in mental and nervous cases—the greater the number of correct diagnoses we shall make, and the greater our success in treating these distressing conditions.

Doctor La Fetra's closing remarks are significant and to the point.

PROGNOSIS.

As to prognosis, few men can speak with more authority than Finkelstein, the German pediatrist, who states that the unfavorable opinion generally held with regard to the fate of congenitally syphilitic infants and children, is in no way confirmed by exact statistical observations and studies. These children may not only become healthy, but may grow up to become robust individuals and useful members of the community. The number of weaklings and anemics is no greater than among those free of syphilis. A similarly optimistic view is held by Baginsky, Heubner, and others.

The mortality in congenital syphilis is highest during the first year and decreases from month to month, in the first twelvemonth. Kassowitz found that thirty-four per cent. of all children with congenital syphilis died during the first few months of life. Werner found, among sixty-seven children born at term, that forty-eight, or seventy-two per cent., died in the first year. In a foundling asylum in Budapest, of 178 children, eighty died of congenital syphilis—forty-six per cent. The unfavorable environment of these children is in part to blame for the high mortality. On the other side, Hochsinger, of 263 children with congenital syphilis, reported a death rate of thirty per cent.; 14.5 per cent. of them died in the first year of life. Pott, in his private practice, had a death rate of twenty-one per cent.; in dispensary practice, the death rate was only eight per cent.; but a great many of the latter were seen but once. He believes that, roughly speaking, two thirds of congenitally luetic children remain alive.

Concerning the influence of congenital syphilis on the mortality of breast fed infants, the statistics of Waldvogel and Suessenguth show that the disease is not productive of a greater mortality in suckling infants, than are other diseases. Nineteen and a half per cent. of their cases of congenital syphilis ended fatally in the first year of life, whereas 18.8 per cent. of breast fed infants died during the first year, of diseases other than syphilis. The difference is so small as to be negligible. Peiser attributes the mortality in syphilitic breast fed infants as much to nutritional disturbances as to the syphilis itself.

Death may result directly from the luetic infection, or it may be due to intercurrent diseases which gain ascendancy in the weakened body of the infant. "The children die," says Heubner, "not of syphilis itself, but as a result of general asthenia, without anatomical lesions; an attack of dyspepsia or bronchial catarrh may eventuate into a fatal illness." The most frequent cause of death, according to Monti, is bronchitis and pneumonia. Of seventy-nine cases, Hochsinger found the cause of death to be syphilis in thirteen, pneumonia in seventeen, meningitis in seven, and intestinal catarrh in eight.

J. Neumann found that if the infection of the mother took place before conception, the mortality was sixty-five per cent. and the morbidity seventy per cent. If infection and conception were simul-

taneous, the mortality was seventy-five per cent., the morbidity ninety-one per cent. In postconceptional syphilis, the mortality was 38.8 per cent. and the morbidity, seventy-two per cent. Finger found that if the mother was infected before the fifth month of gestation, there was a fetal mortality of seventy-eight per cent. and a morbidity of 100 per cent. According to Etienne, the mortality of infants born to untreated syphilitic mothers may reach ninety-five per cent. If the prospective mothers receive adequate treatment, however, the death rate may fall as low as ten per cent.

According to Kassowitz, the prognosis becomes more favorable, the older the child is at the time of the first appearance of luetic symptoms. Among 172 cases, Diday and Roger found that the first symptoms appeared ninety-two times in the first month, sixty-seven times in the third, seven times in the fourth, once in the fifth and six months (respectively), and four times after the sixth month of life. Roger bases his prognosis on the clinical findings in the child at its birth. If it is born with signs of active syphilis, the outcome, in his experience, is usually fatal; if the child is born apparently in good health, but exhibits the signs of active syphilis within a few weeks after birth, adequate treatment will usually restore it to health. Syphilitic disease of the central nervous system and of the viscera in the newborn, spells early death.

In older children, the effects of congenital syphilis have been studied by a number of investigators. Peiser reported his findings in a series of 101 children, whose histories he was enabled to follow for several successive years. His conclusions are, that the prognosis for older children is by no means as gloomy as is commonly thought to be the case. Of fifty-nine children who had been kept under surveillance after they had reached the second year, he found twenty-three in excellent general health, twenty-two in poorer, but still fair health, and fourteen in poor condition. Six of the children were imbeciles. (The serological findings are not given.)

The relative innocuousness of late congenital syphilis is well illustrated in two patients under my care in Doctor Fordyce's service. One was a girl, about twenty-one years old, who applied for the treatment of a severe acne of the face, but who was otherwise in apparently perfect health. She was unmarried. When she smiled, it was seen that her two upper incisors were deeply notched. Her teeth were so typically Hutchinsonian in type, that a photograph of them was added to Doctor MacKee's collection. A blood test revealed a 4 plus reaction. There were no other stigmata of syphilis. She refused to submit to treatment, and the last time I saw her, the notched teeth had disappeared and were replaced by two beautiful porcelain substitutes. The other case was a married woman, who brought her two boys to the clinic for the treatment of ringworm of the scalp. By accident, it was noticed that she also presented a pair of typical Hutchinson teeth. She said she was in perfect health and looked the part. She had had no miscarriages. Her Wassermann test was 4 plus. The children's blood tests were negative and they were healthy. Strange to relate, this woman also had one of her incisors replaced by a gold tooth, and she recently informed me that she was laying aside enough money to pay for its mate.

A very instructive résumé of the subject of syphilitic heredity and congenital syphilis was recently contributed by Boardman (9), of Boston, and I borrow freely from this article in the following quotations:

> Engel and Reimer state that children showing symptoms in the first four weeks of life, nearly all die; of those showing them in the second month, two thirds die, and in the third month, about a half die. Only about twenty-eight per cent. of children born syphilitic survive the first year. As to the Wassermann reaction in the newborn—Müller gives a large series, showing that in those infants with active symptoms nearly all are positive, almost the only exceptions being those who are immediately overwhelmed with the disease and die almost at once, or in a day or two. Those children born apparently healthy, but of syphilitic mothers with active signs or a positive reaction, show a positive reaction in about forty per cent. of cases, but many more develop a positive reaction in a few weeks or months, often accompanied by the onset of syphilitic symptoms. It is more frequent in the children born of mothers showing active symptoms during pregnancy than in the children of latent syphilitic mothers, but the difference is not startling. Children of mothers who have had syphilis, but at the time of pregnancy show a negative reaction, show a positive in only 12.5 per cent. of cases, increasing somewhat as the child grows older or as active syphilitic symptoms develop.
>
> The number of negative reactions persisting with no signs of syphilis in the child suggest that these are exceptions to Profeta's law, that the apparently healthy child of the syphilitic mother cannot contract syphilis, though this may not hold throughout the child's life. In other words, the child of a syphilitic mother is always syphilitic. Bertha Sabin has gone into this subject very carefully in the past year (1913). She concludes that where the mother has syphilis at the time of conception, or acquires it in the first five months of fetal life, the child is almost invariably syphilitic; in the sixth month it is only probable; after the sixth month it is rare, but there are exceptional cases of infection of the child when the mother contracts the disease even later. These late postconceptional cases are therefore the only exception to Profeta's law, and the other children are really cases of latent congenital syphilis, though there are no signs of the disease, and the Wassermann reaction is consistently negative for months. Clinically, practically the only exceptions are these postconceptional cases. We should, therefore, in such cases try the Wassermann reaction in the infant, and examine the placenta and cord, if the child shows no signs of the disease clinically (Poppi). This will show the presence of syphilis in a large percentage of cases, and if it does not, and the case is one of late postconceptional syphilis, the child should not be allowed to nurse, as infection from the nipple is not too rare in such cases. In regard to the Wassermann reaction made later in life, in these syphilitic children, Churchill, Kellner, and others have noticed that it begins to disappear after four or five years, in spite of the persistence of perfectly definite stigmata, though it nearly always reappears with the appearance of active symptoms of the disease.
>
> Many authors lay great stress on the value of examining the placenta and cord histologically and bacteriologically. Wersilova found spirochetes in the placenta or cord in 62.5 per cent. of cases, and Grafenburg in fifty per cent.

Ernst Welde (10) says that from 1902 to 1910, inclusive, 100 cases of congenital syphilis were treated in the wards of the Berlin Charité Hospital, and 296 cases in the polyclinic. As the task of tracing the entire 396 cases was impossible, Welde arbitrarily limited his studies of end results to the 100 cases observed during 1902, 1904, and 1908. Even by securing the assistance of the police, Welde could succeed in discovering the addresses of but

sixty-eight per cent. of the total cases. Of this number, forty-one per cent. were reported dead, twenty-seven per cent. presented themselves for re-examination, and thirty-two per cent. made no answer to inquiries.

The second series of investigations included 200 cases, 100 from the hospital and 100 from the polyclinic. The mortality was found to be seventy-four per cent. among the hospital patients and thirty per cent. among the cases treated in the polyclinic. These statistics are valid only for the hospital, not for congenital syphilis at large. If it was possible to add the cases in private practice (as Welde argues ought to be possible), mortality percentage would be considerably reduced. The low death rate in the polyclinic, compared to the very high percentage in the hospital cases, is explained on the ground that only severe cases are admitted to the wards. Poverty with its associated ills, poor physical condition and severe infections, contributed to produce the high rate of seventy-four per cent. mortality. The thirty per cent. mortality among the polyclinic cases was needlessly high, many cases having been brought to the polyclinic but once. If the parents, instead of resting satisfied at learning the diagnosis, had brought their children for continued treatment, many would undoubtedly have been saved from death.

Welde made an interesting study of the relation to prognosis of the time of the first manifestations of syphilis. He reports that thirty-five per cent. died, of those who presented symptoms at birth, forty-two per cent. of those first showing signs during the earlier weeks of life, while, of those who were six months of age or older, before showing evidence of syphilis, only one per cent. had died.

A fourth table shows the value of breast milk very graphically. Only twenty per cent. of the breast fed infants died. The mortality of the artificially fed infants was forty-two per cent. The beneficial influence of human milk feedings is especially well illustrated by the lower mortality of thirty-one per cent. among infants who had received breast milk for even a short time.

Welde presents a table to illustrate the effect of treatment, from which he draws several conclusions. These figures seem to show that the mortality depends less upon the drug or the method, than upon the energy with which the treatment is pursued. It was found that the highest death rate was in the cases which had received the least treatment. In seeking for greater understanding of this fact, Welde discovered that, while in the hospital it was the severest cases which had received the least treatment, the contrary was true of the polyclinic. In the hospital the severity of the infection and the low vitality caused death before it was possible to give adequate treatment, regardless of methods. In the polyclinic, the very mildness of the cases induced neglect. It is a matter of record, Welde reports, that of the 296 polyclinic patients, 114 never made a second visit. He ventures the assertion that one half of these patients, if living, are still syphilitic.

Thirty-six patients were examined for cure, and for the persistence of the disease. As evidence of cure, Welde insisted that the patient should neither exhibit physical signs, nor react positively to the Wassermann test. He found twenty-seven still syphilitic; nine he accepted as cured. In answer to the objection that the Wassermann reaction does not furnish indisputable proof of cure, and furthermore, that it is notoriously slow in disappearing in congenital syphilis, even after abundant treatment, Welde admits the facts, but argues that so long as we cannot explain the reaction, it is best to accept a positive result as an indication of the presence of syphilis. Although but nine cases of cure were found, nevertheless, even this small number is sufficient to demonstrate that cure is not impossible.

Welde's (1) final conclusion is, that everything proves the need of official supervision of every case of congenital syphilis, both in public and private practice.

OUR AMERICAN VOICE AND ARTICULATION.*

By Charles Prevost Grayson, M. D.,
Philadelphia.

In one respect at least I resemble Marc Antony at the bier of Cæsar—I come not to praise. There are, no doubt, certain critical moments in the history of our country when a feeling of reverent loyalty will so tune our ears that even the piercing scream of our national bird will fall upon them as so much celestial music, but surely no amount or depth of patriotism can so anesthetize our ears that they will find anything musical in the voice of the average American, male or female, particularly, if you will pardon my want of gallantry, female. The fact that we are the youngest of the great nations does not excuse this defect. We are certainly old enough to show at least that we are conscious of it and to make some concerted effort to correct it, and it seems to me that the very first step in such a reform movement should be taken by us, the members of this association. It is we who are the self appointed custodians of the larynx and its vocal function and of every nerve and muscle that plays a part in articulation. It would be but a beggarly conception of our responsibility were we to limit it to the treatment of diseased conditions. Wide as that field is, our field of endeavor should be wider, and, to my

*Read at the annual meeting of the American Laryngological, Rhinological, and Otological Association, White Sulphur Springs, W. Va., May 6, 1916.

mind, it should include to a reasonable extent the education of this complex mechanism. As a brief preliminary to this main purpose of my paper, will you permit me to summarize certain activities of rhinolaryngology during a number of years past? I would refer particularly and only to those surgical achievements that are closely related to my subject.

Probably more than to anything else our surgical skill has been applied to the removal of obstructive conditions of the upper air passages. The nose having been recognized as an essential and most important part of both the respiratory and phonatory mechanisms, every abnormality, mechanical or pathological, the effect of which was to cripple nasal breathing or to impair tone quality, has met with and yielded to its appropriate operative procedure. The conquest of adenoid growths is an old story, and we are now at the very crest of so vigorous a crusade against the tonsil that, were Nature easily discouraged, it would be threatened with extinction. All that has been accomplished in this way has been not only of distinct advantage to the voice by providing it with the full amount of resonating space that Nature intended it to have, but it has also directly contributed to the prophylaxis of ear disease. And, apropos of the ear, it is also closely relevant to my subject to recall the remarkable progress in the instruction of the deaf. This has occurred largely through the instrumentality of otologists. Without engaging in any actual warfare upon the empiricism of the many lay teachers of the deaf, they have quietly effected a remarkable evolution in methods through the gradual establishment and introduction of scientific principles and their application by an almost standardized system. We need no better evidence than the results that have been accomplished, that the individual who is seriously or totally deaf has aroused a compassion that is practical as well as sentimental.

It may have already occurred to my readers that my hurried review of these features of our work has had for its purpose the drawing of a contrast. I have wished to make it as strikingly evident as possible, that while we have been doing so much for the education of the deaf and for the relief of those suffering from respiratory and phonatory embarrassment, we have done practically nothing as yet of an educational nature for the cultivation of the voice or the refinement of articulation. Shall I be met with the reply that this is not our work, that when we have brought the vocal apparatus to a state of health and efficiency, our interest and our professional responsibility cease? Will it be said that we have no concern with the correct use of the voice, with distinct articulation, with careful modulation? Will it be contended that these matters belong exclusively to the realms of art and esthetics, that the field of medicine is purely materialistic and has no place for them? I have no apprehension that any such opinions will be advanced. Nothing is more clearly recognized than the absolute interdependence of a sound larynx and a sound voice, but I realize that opinions may vary within wide limits as to what constitutes a sound voice. I confess that I am not one of those who seem content with the almost simple, uncolored fundamental tone as it comes naked from the vocal cords. Is it too much to hope that some day we may have an American voice that will be clothed with its full complement of overtones, with all the resonance that Nature intended it to have, and with a delicacy of modulation that will adapt it to every occasion? I deny in advance of the assertion that such a hope is Utopian. It may and no doubt will be difficult and slow of realization, but that is true of almost everything that is worth hoping for and having.

That which may seem impracticable at first thought is really little, if any, more so than any other branch of a common school education, and in that nutshell of a sentence lies the whole kernel of this paper. I say, and I think that we all should unite in saying, that vocal instruction should be introduced and made an essential part of the curriculum of every school, public or private; that every child should not only be taught to use his voice correctly, but that he should be as rigidly marked for his proficiency or his lack of it as he is for any other of his studies. Nor should this teaching be limited to the elementary schools. It should be continued with equal insistence in the high school, the college, and the university. By vocal instruction I hope no one will suppose that I mean singing or elocution. Those are highly developed specialties that would properly fall within the domain of postgraduate and individual instruction. I only mean that the child should be taught the art of ordinary speech, an art that should not be regarded as an accomplishment for the few, but as an essential feature of the education of all. That the earlier in life it is taught the more easily it is acquired needs no saying, and with the gradual growth of the child's vocabulary it is no less important and no more difficult to teach him distinct enunciation than correct pronunciation. Why do we insist upon the one and utterly neglect the other? Why be content with the half loaf when we can as easily procure the whole? Is it of any advantage or consolation to a listener to know that a speaker gives emphasis to the proper syllable of a certain word if all the other syllables are lost in inarticulate confusion? Much of the criticism that is levelled at our manners and customs by our British cousins we can afford to take good humoredly and without resentment, if not, indeed, with a certain amount of disdain, but there is one criticism that irritates me, at least, beyond measure, and that is that our speech is often referred to as American English. It is a hyphenated language that we are accused of speaking. Why? Not, let us hope, because our command of English is any less complete than theirs, nor that, as to the meaning of words, we use them any less accurately than they, but largely because, through indifference and lack of proper training in childhood and youth, we slur and clip and muddle our syllables to such an extent that the words of which they are parts become more or less unrecognizable. I have no intention of discussing the justice or injustice of this accusation. I only mention it as one of the smaller and less important stones in the foundation of the argument that I am building. With the teaching of grammar and diction and literary style, we have no professional concern whatever, but with the safeguarding of the larynx

through the normal development and proper use of the voice, who has more than, or even as much concern as we? It needs no exhaustive analysis of the relative importance of the several fundamental branches of education to establish the value, as a practical and dividend bearing asset to any young man or woman, of a properly pitched voice and a distinct utterance of words. I am not considering it from an artistic but from a strictly utilitarian point of view.

The typewriter has been a Godsend in protecting us from the time waste and temper torment of illegible handwriting, but no mechanical device can ever protect us from the offense of slovenly and unintelligible speech. Our only hope for relief from that evil comes from careful and competent instruction of the young. There, we shall probably all agree, is the rub. Where are we to find competent instructors? Unfortunately, they are not easily found, but, fortunately, they can, unlike poets, be made. It is no more true that necessity is the mother of invention than that competition is the parent of competency, but if the hundreds of young men and thousands of young women in our high and normal schools, who are looking forward to the profession of teaching as their life work, are told by our county and municipal boards of education that their appointment as teachers will largely depend upon the clearness of their voices and the distinctness of their enunciation, we may be confident, I think, that within a brief period there will be a very marked improvement in these respects. Naturally, no one will expect these young people to give any technical instruction concerning voice building, or voice production, but they can teach, both by precept and example, correct articulation. The child labor laws that are now being rapidly enacted in the various States of the Union make it possible, compulsory, in fact, that for at least six or eight years of his life every child shall attend school. It seems to me that there can scarcely be a reasonable doubt that if throughout this long period the child lives in an atmosphere of distinct speech, if he constantly hears and is himself compelled to practise it, the habit will be formed and become so firmly established that it will remain a permanent one. No one realizes more fully than I do the many and serious difficulties that may impede the addition of what seems at first thought so unimportant a detail of education to the course of instruction covered by our public schools, but we have learned so often during the past half century that the impossibility of yesterday is the reality of today, that I am encouraged to hope that this valuable and easily acquired grace of speech may be one of the bright realities of tomorrow. I am not disposed to be oversanguine, and by tomorrow I mean only within the next two or three generations. We may not, in all probability we shall not, live to see more than the bud that will denote the future fruit of our labor, but in taking leave of it we may at least have the satisfaction of knowing that we have started a phonetic reformation that, perhaps, physicians yet unborn may carry to successful completion. As to methods, I have no thought either of asking for the appointment of a committee or of suggesting that we should enter upon any carefully planned campaign. On the contrary, I think it likely that we should accomplish much more individually than collectively, that each of us, in his own city and State, would exert greater influence in promoting such a cause than could any documentary appeal issuing from us as a body and addressed to the country at large. In spite of the powerful and distinctly special appeal that this subject should make to the laryngologist, it will be, I am afraid, a long time before it arouses, even in him, anything more than an abstract and languid interest. It is but a commonplace to say that nothing so promotes the health and functional vigor of the larynx as cultivation of either the singing or speaking voice. In all probability there is scarcely a day that each of us does not warn one or more of our patients of the injury they are inflicting upon their throats by some more or less glaring misuse of the voice. How much better would it be to render such warning entirely unnecessary by beginning the prophylaxis of the laryngeal trouble and the conservation of the voice before any material harm was ensued, before bad vocal habits have been formed, and while it is still easy to form good ones! It is a matter, a mission indeed, the furtherance of which should enlist not only our professional but our national pride.

VINCENT'S BACILLUS IN THE CERVIX.

By Guthrie McConnell, M. D.,
Waterloo, Ia.
(From the Clinical Laboratory of the Waterloo (Ia.) Medical Society.)

Although there is some dispute as to the pathogenic properties of the fusiform bacillus, it is so constantly present in cases of Vincent's angina that there can be little doubt of its being an active agent in inflammation. It has been found so commonly in inflammatory conditions of the mouth that the general idea is that it does not occur anywhere else, yet such is a mistaken opinion. It was first noted in cases of hospital gangrene, but in addition to tonsillar conditions it has been reported in ulcerations of the penis, appendicitis, gangrene of the lungs, putrid bronchitis, and Heurlin reports finding it in the vaginal secretions of a normal woman.

The following case, for which permission to report is due to Dr. J. E. Brinkman, is interesting mainly on account of the site of the lesion. Attention was called to it by a smear that was sent to the laboratory for examination. The report returned was to the effect that practically no other forms of organism were found than the fusiform bacillus and the spirillum. The diagnosis of Vincent's angina was offered, the laboratory not knowing where the smear was made. A brief history of the case is as follows:

Case. Mrs. L. C., aged twenty-seven years, white, five years ago, had a child. Delivery was normal, but patient said that at that time she was infected. Since then she had been troubled by a vaginal discharge which varied in amount and in color, sometimes whitish, other times greenish, occasionally irritating.

In September, 1915, she had a very sudden and severe attack of sore throat. She had been more or less subject to them, but this was the worst. Was painful, so much

so that swallowing was difficult. Following this there was an increase in the amount of vaginal discharge, which by the first of February had become profuse and irritating.

In March, 1916, she came for examination and treatment. At this time the cervix was found to be free from tears, but it was reddened and edematous. Surrounding the canal there was an area of superficial erosion about one inch in diameter.

The treatment consisted of painting with iodine and the application of boroglyceride tampons containing ichthyol, iodine, and phenol. In the course of a little over two weeks five treatments were given with much benefit. The patient then left the city.

There is, of course, no way of proving that the cervical infection was in any way due to the throat conditions, particularly as no microscopical examination was made at the time although the symptoms as given were typical of Vincent's angina. It might well be that there was more or less erosion of the cervix following childbirth and that the tissues were then more susceptible to the fusiform bacillus. Whatever the method of infection, the fact remains that microscopical examination of the smear showed an almost pure growth of the fusiform bacillus and its accompanying spirillum.

HEALTH INSURANCE FROM THE VIEWPOINT OF A PHYSICIAN.

By A. C. Burnham, M. D.,
New York.

The rapid spread of workmen's compensation insurance throughout the United States during recent years has clearly demonstrated the important economic role which the physician is called upon to assume in the management of accident cases of industrial origin. From a financial standpoint this has been of great importance to the medical profession, which, until the various acts became laws, was decidedly apathetic toward the whole subject, apparently knowing and caring very little what arrangement the State might make to care for the sick and injured among its vast industrial population.

It is impossible to say what the changes taking place in our modern life may portend. Such laws might conceivably be the beginning of what in the end will result in a system of treatment of everybody by physicians in the employ of the State and the consequent complete disappearance of the private practitioner. While such a result seems hardly conceivable, yet it takes only a superficial examination of the activities of the various boards of health and State health departments to bring about the conviction that the activities of the private physician and private medical enterprises are being gradually curtailed in favor of the physician in employ of the community. That this in the main makes for increased healthfulness of the community and consequently increased efficiency of the individual is not to be denied. In New York city the board of health supplies diphtheria antitoxin to the public, thereby preventing the spread and lowering the mortality of the disease. In some cases the diagnosis is made and the antitoxin is administered by a physician of the department. If this is right and proper, why may not the State supply the physician with a diagnosis of malaria and rheumatism, and give quinine and the salicylates when indicated?

Following the introduction of workmen's compensation insurance, with the accompanying State control of the medical care of industrial accidents, the next step would logically be State control of the health of industrial employees, and, possibly later, the care of the health of the workman and his entire family. Still later, this same system might be extended to include the entire community. Fortunately at present we are not called upon to decide the advantages and disadvantages of such a system along its broadest lines, but have to do merely with the care of the health of the workman, in some cases including his dependents.

In order to accomplish this end a tentative plan[1] of an act has been formulated by the American Association of Labor Legislation and introduced into the State legislatures during the present year, which contemplates the care of the industrial employee and his family during illness and which is entitled Health Insurance.

If the experience of Germany, England, and other European countries is of any value to us, it is safe to assume that such an act will soon be found among the laws of many States, and, again reasoning from the experiences of other countries, it is important that the medical profession, as one of the parties chiefly concerned in the administration of the law, should make its influence felt for a satisfactory, practicable law, allowing maximum benefits to the patient, suitable remuneration to the physician, and a minimum expenditure by the State.

Such a law will mean that much less of the physician's work will be done for charity; the State saying, in effect, that workmen are not paupers and that medical treatment is their right and due, thereby creating a large class of private practice, which, previously, has for the most part received no care at all, or, at the best, only a desultory and ineffectual treatment. The care contemplated will represent the expenditure of a large sum of money and it is to the interest of the medical profession to see that this money is wisely spent, the patient and the State receiving the maximum benefit.

It must be stated at the outset that the physician and medical societies (although they derive great benefits from such an act) are not considered as beneficiaries under the act. The physician should realize that it is merely an accident that he plays such an important part in the administration of the various plans of health insurance. Compensation is not a method of taxing a rich employer for the benefit of the physician and the patient; nor is it a means of equalizing the monetary differences between the employer and the employee. It is an attempt to place the burden of the result of accident and ill health upon the community as a whole.

Bearing in mind this broad conception of health insurance, a brief résumé of the tentative act as drawn up by the Committee on Social Insurance will be of interest. The draft of the act is divided into fifty-three sections, the first fifteen of which are of greatest interest to the medical profession. Sections

[1]Copies of *Health Insurance Standards and Tentative Draft of an Act* may be secured from the Secretary of the American Association of Labor Legislation, 131 East 23rd Street, New York.

1 to 5 outline the name of the act and designate the persons insurable under the act. Among the provisions is included the compulsory insurance of every person in the State at manual labor under any form of wage contract, whose remuneration does not exceed $100 a month, together with voluntary insurance of certain persons not included under the foregoing. Federal employees, for obvious reasons, are excepted.

Sections 6, 7, and 8 outline the benefits of the insurance, which, as a rule, begin the first day of employment, and are provided in all cases of sickness, accident, or death not covered by the present Workmen's Compensation Act. The following are prescribed as the minimum benefits: Medical, surgical, and nursing attendance; medicines and surgical supplies; cash benefits; maternity benefits; funeral benefits; medical and surgical attendance; and medicines for dependent members of their families.

Section 9 provides for medical, surgical, and nursing attendance for a period of twenty-six weeks, and section 10 provides for medical and surgical supplies, not to exceed $50 in cost in any one year. Hospital treatment, when indicated, is provided for (Section 11) instead of other benefits. A cash benefit equal to two thirds the weekly salary is provided for (Section 12), payable (Section 13) from the fourth day of disability.

Insured women and the wives of insured men are entitled to maternity benefits (Section 15), which consist of medical care and supplies, and a weekly cash benefit for a period of eight weeks. Funeral benefits (Section 16) and in some cases other benefits are provided by the insurance carriers.

The expenses are to be divided between the employer, the employee, and the State (Section 18), and insurance is to be carried by either, 1, the State, 2, approved societies as in England, or, 3, mutual associations as in Germany. The remainder concerns itself chiefly with the administration and execution of the act and consequently its provisions are of importance from a legal rather than a medical point of view.

Only a brief perusal of the foregoing suffices to point out the socialistic tendencies of such a law. This is granted, but the possibility of the passage of some modification of this act is undisputed, and if the experience of foreign countries is of any value, we may expect such a law in some of the States in a comparatively short time.

From a theoretical viewpoint, in such a law the medical care of the insured may be provided for under one of three different plans of procedure:

1. The method of free choice, by which the employee is allowed to choose his own physician, the fees being paid by the insurance carrier.

2. The contract method, by which physicians are allowed to contract for their services at a certain annual or semiannual per capita fee.

3. The method of State control, under which the State may appoint a panel of physicians, either as full time officers of the State, or under a fee system to be decided upon.

Before discussing these methods it would be well to outline the ideal requirements of such a medical service.

A. To the patient:

1. As rapid a recovery as is compatible with the nature of the disease.

2. The maximum cooperation and sympathy between physician and patient.

3. Accessibility of medical advice and treatment.

B. To the physician:

1. Adequate remuneration for services rendered.

2. Complete control of both the treatment and the environment.

3. Sufficient medical supplies and hospital facilities.

4. Consultation with and treatment by specialists when indicated.

5. Satisfactory clinical records.

6. A minimum of clerical and administrative duties.

C. To the State:

1. The minimum period of disability.

2. The minimum expense for medical care and administration.

3. Complete statistics upon which to base the annual premium as an indication of necessary improvements in the law and as a preventive of abuses which may arise.

Bearing these requirements in mind, we may now consider the various methods for the medical care of the insured.

The first method, the so called method of free choice, has for its chief advantage the sympathy and cooperation existing between physician and patient. The employee, being permitted to choose his own physician, is more ready to cooperate with him in his treatment; the consequence is often a better therapeutic result and a more rapid convalescence. There are many disadvantages, however, which far outweigh the benefits derived from this method. In the first place, the choice is apt to be made because of social qualifications or individual preferences rather than professional capability. The ordinary industrial worker has little opportunity to inquire into the professional qualifications of his physician, and is apt to make his choice because of the recommendation of a friend or as a result of the rosy promises of the advertising quack.

The remuneration of the physician is usually ample in these cases, but the unscrupulous practitioner takes advantage of the fact that he is working for the State and makes unnecessary visits and prescribes expensive medicines because, in the common parlance, he can get away with it.

Clinical records are rarely kept in these cases, and statistics are of little value because there is no standardization of reports. Moreover, the clerical duties are irksome to most physicians and are partly or wholly neglected.

The final result of this system is that the State pays considerably more than is necessary for medical attention, which is unsatisfactory; little or nothing is added to the sum of medical knowledge, while many truths, which would tend to bring about the betterment of humanity as a whole, are hidden among a mass of facts which cannot be correlated.

The system of unlimited choice was adopted by France, in 1905, and, as a result, abuses have arisen which are almost inconceivable. The following ex-

tract from an article by H. C. Villard[2] is of sufficient interest to be worthy of quotation in full. In reference to the formation of private clinics, which were formed in great numbers after the law was passed, he says in part:

> Usually these (clinics) were started by young and unscrupulous doctors with little standing and practice and indifferent to the established rules of medical ethics. As the accident insurance made the employers responsible for all medical costs and fees, these practitioners foresaw that, once assured of a clientage, their path to fortune was secure. Accordingly, while self advertising is deemed highly unprofessional in the best French medical circles, the owners of these private clinics have not hesitated to use the most flamboyant and often dishonest methods to attract to their establishments workmen who have been injured in the course of their employment. Drummers and agents are posted and employed near important workshops, whose duty it is to steer injured workmen to, and to extol the merits of these clinics. The clinics themselves are painted in gaudy colors, flaring advertisements are posted in conspicuous places, circulars are sent out, and handbills distributed among the working classes. Dressing of wounds, massage, electricity, radium, and mechanicotherapeutical treatments are offered. Attention is also called to the fact that attached to the clinic is a legal bureau which will procure the maximum indemnity allowed by law and attend to all formalities prescribed for the procuring of the same. Certain of the clinics have even gone a step further and now bestow a five franc piece on an injured employee when he first presents himself and allow him a daily stipend ranging from one half to two francs a day so long as he is under treatment. With such inducements, it is not surprising that the workmen, when injured, flock to these private accident clinics. In Paris, more than half of all accident cases are treated in them.
>
> The bad results, of the provision in the French accident insurance law granting to the injured workman the right to select his own physician, are thus apparent. The individual practitioner does not benefit, for he finds no accident cases coming to him for treatment. The workmen are demoralized, for they have been taught not to regard an injury or disability as a misfortune, but as a means of making something out of their employers. Hence their readiness to travel even a distance of fifty miles from their places of injury to the clinic that holds out the most inducements. The employers and insurance companies are fleeced at every possible turn, and a heavy burden is imposed on French industry in the shape of increased premium rates.

As a corollary to the method of unlimited choice by the employee is that of unlimited choice by the employer and it is this method under which the present New York Workmen's Compensation Law is administered. This has already led to many abuses, chiefly because the small employer transfers the responsibility to the employee, and in most cases the final result is the same as though the employee were given free choice in the first place. In the case of larger employers the situation is under better control, and the excessive abuses occurring in France will probably not be duplicated here.

The second method is known as "the contract system" and in this the medical care is undertaken at an annual per capita rate. The contracts may be made by the insurance carrier, the employer, or by the local fraternal associations. In this the physician undertakes to give unlimited attendance for a fixed fee, which is naturally a physical impossibility. Unscrupulous physicians underbid each other until the result is a remuneration barely sufficient for rent and living expenses, and the physicians, in order to increase their income, must search outside of their legitimate practice. They charge large fees for special treatment not included under the law; special unnecessary consultations and operations add further to their incomes. It is to the physician's interest under this plan to make as few visits as possible; to send patients to the hospital upon the slightest provocation; to keep few records and, in general, to give as little attention to his contract patients as the law will allow, devoting the major portion of his time to his private practice. This system is unsatisfactory to the patient, to the honest physician, and in its final result, to the State. The chief advantage is that it is cheap and easily administered.

An attempt is often made to correct these errors by limiting the number of cases treated by any one physician and fixing the per capita fee at a sufficient amount to compensate the physician for the time spent. It is this method which is the cause of considerable dissatisfaction in England at the present time. The physicians are generally fairly well paid under an agreement between the Government and the British Medical Association, but the system lacks elasticity and there is a great deal of complaint because of the clerical work which it entails. Patients complain that they are rarely examined, and that their treatment is unsatisfactory. Moreover, under the law, their treatment is limited to ordinary medical care which the physicians interpret as excluding special treatments and even the smallest surgical procedures. As a whole, the contract system is a failure, except in the hands of specially conscientious physicians, and even under State supervision its control is difficult.

The method of State control seems to overcome many of the difficulties seen in other methods. Its chief disadvantage is that it may come under the influence of politics, and as is the case in most political enterprises, is apt to be open both to inefficiency and graft. Under civil service, however, and the appointments made for long periods, this disadvantage becomes less obvious. The State may successfully assume the medical care of the insured under such an act only when it has full choice of physicians employed who are directly answerable for their conduct to the State authorities. One method of securing these results is by the appointment of a panel of physicians who may or may not receive a nominal amount, but who are compensated in the main by the payment of a stipulated fee for each visit or office consultation. In this plan the insured may or may not have a choice of physicians among those on the panel, each physician acting independently. There is a certain amount of elasticity, and in general the conditions make for satisfactory treatment of the insured. The administration and medical expenses of such a plan are apt to be high, but it attracts a better type of physician than the other plans and the relation between the patient and physician is well preserved. Records and statistics, however, are kept only with difficulty, and there is a waste of energy and, in consequence, an increase in expense which might be prevented. This system of limited choice is undoubtedly the best in rural districts, and fairly satisfactory for the administration of an act such as the present Workmen's Compensation Act, which includes the medical care

[2] New York *Evening Post*, April 12, 1913.

of only a comparatively small part of the entire population; but if we are to care for every member of the family of each and every person earning less than $1,200 a year, we have a much larger problem before us, and it is important at the outset that the work be undertaken systematically and with definite ends in view, rather than in a hit or miss manner, leading later to abuses which can only be eradicated after a long period of inefficiency.

The systematic care of the industrial population on a large scale can be accomplished only by means of State control through a department modelled somewhat along the lines of the medical department of the United States Army, having hospitals, full time medical officers, nurses, and other necessary medical employees.

Such a plan might be briefly outlined as follows: The State would be divided into districts, and a medical unit having full care of the insured, would be assigned to each district, the insured being directed for treatment to the headquarters of the unit having charge of the territory in which he lives. Specialists would be in attendance at certain hours and on call when required. Regular attendance upon the patients by the visiting physicians would be assured, the physician being sent from the medical centre upon request. The clerical work would be done at the various centres by the lay employees, all records and statistics being compiled easily and comparatively inexpensively.

If, in such a system, the salaries were made large enough, permanency of position was assured, and opportunity of advancement permitted, many physicians would be eager to choose just such a career. This system would, as a rule, assure quicker convalesence and more scientific treatment of the insured, pleasanter and more satisfactory work for the physician, and, I firmly believe, cheaper and better results for the State.

It is necessary to emphasize the fact that, in this paper, the writer has attempted to discuss only the more salient abuses occurring in the administration of the benefits of health insurance, as well as to indicate the solutions of only a few of the problems which may arise. If we are to have health insurance, it is desirable that the physicians make as few mistakes as possible, the ideal time to rectify a mistake being, paradoxically, before it is made. Numerous details still remain unsettled even in those countries where health insurance has been under trial for many years. The efficient methods of Germany have been unable to eradicate the errors of omission and commission incident to the management of a national health insurance act, already on trial for over thirty years, mainly because of abuses which crept in after the establishment of the law. If we are to hope to benefit by the mistakes of others, a full discussion of the entire subject is desirable, and it is earnestly urged that this discussion take place before the Health Insurance Act is passed—not afterward.

MODERN METHODS OF TRANSFUSION.

By L. Miller Kahn, M. D., F. A. C. S.,
New York,
Adjunct Attending Surgeon, Lebanon Hospital.

That the modern methods of transfusion have had many and similar predecessors is attested by the immortal Pepys, who on November 14, 1666, wrote in his diary that "at a meeting at Gresham College . . . there was an experiment of the blood of one dog, let out, till he died, into the body of another on one side, while all his own ran out on the other side. The first died upon the place and the other very well and likely to do well." On November 21, 1667, Pepys wrote of a "poor and debauched man that the college had hired for 20s. to have some of the blood of a sheep let into his body . . . their purpose to let in about twelve ounces which they compute is what will be let in in a minute's time by the watch." This transfusion, the first ever done in England, was accomplished by means of a cannula at a meeting of the Royal Society at Gresham College on November 23, 1667. It was successful, for on November 30th, Pepys recorded that "he was pleased to see the person that had his blood taken out and that he finds himself much better since and as a new man." It will be observed that this early attempt at transfusion was based on careful animal experiments, was done by cannula, and that a method of computing the amount of blood given was based upon the quantity that a sheep's artery would bleed in one minute. This lacked, therefore, only the laboratory report on the hemolysis and agglutination tests between the donor, in this case a sheep, and the recipient.

A further study of the history reveals the reasons why transfusion was not feasible until within the last few years. The blood clotted in nearly all the attempts, or when partly successful mechanically fatalities often followed the transfusion, owing probably to blood incompatibility. Transfusion became an accomplished fact only when certain conditions were fully satisfied. These conditions are of two kinds, physical and biochemical. It was necessary, when direct transfusion was done, to keep the blood circulating, direct transfusion being any method in which the blood flows directly from the vessels of the donor into those of the recipient. Direct transfusion could be accomplished, therefore, only if means were found to prevent clotting. One important step was taken in this direction when Alexis Carrel (1) perfected his method of blood-vessel anastomosis. By means of paraffined sutures and with the discovery that suture of intima to intima was the correct procedure, transfusion as a mechanical fact was accomplished. Then followed the invention of the Crile cannula, a device which overcame many of the technical difficulties of bloodvessel suture. The Crile (2) cannula is a small metal tube so arranged that by passing a section of the recipient's vein through the tube and reflecting a cuff, the artery of the donor may be drawn over the cuff of the vein, thus bringing intima to intima. Brewer (3) devised a glass tube coated with paraffin which was introduced into the

vein of the recipient and the artery of the donor. The paraffin in the tube permitted the blood to flow for a considerable time without clotting. Both methods were improved upon, the best instrument for bringing the vessels into apposition being the Elsberg (4) cannula, which overcame many of the defects of the Crile instrument. Briefly it consists of two halves of a small tube, each half being attached to an upright piece. These upright pieces slide on each other by means of a thumb screw, thus enabling one to make the cannula any size. Upon each half of the cannula are small hooks; the artery is exposed and the instrument opened wide and slipped under and around it: A cuff is turned back and caught on the small hooks, and when the recipient's vein is exposed and opened, the cannula with the artery in place is slipped into it and tied. The Brewer paraffined glass tube was improved by Bernheim, of Baltimore, who constructed a silver tube in two sections, one half to be inserted into the artery of the donor, and the other into the vein of the recipient. When both were ready the two halves were joined and the blood was allowed to flow. This method worked as nicely as any such method can. Tuffier and Carrel devised a small metal tube of comparatively large calibre intended to accomplish the same result.

All these methods are open to the following objections. First, the procedures are difficult and require a high degree of special skill; second, there is inability to measure the amount of blood transfused; and, third, simpler and more efficient methods have been devised.

Many difficulties of direct transfusion were instantly overcome by the introduction of the syringe-cannula method of Lindeman (5), indirect transfusion. This consists of the introduction of cannulæ into the veins of both recipient and the donor. This can be done in most instances merely by skin puncture, then by means of a number of syringes and with the aid of several assistants, the blood is rapidly withdrawn from the donor and injected into the recipient. It is necessary, in the intervals between withdrawals from the vein, to inject saline solution to prevent clotting, but if a sufficient number of syringes are available and the team work is perfect, 500 to 1,000 c. c. can be transfused in a few minutes. Great care is taken in cleaning the syringe after an injection and before using it the second time. This method and its modification, the Unger method, have the great advantages of certainty of success with very little practice and absolute knowledge of the quantity of blood injected.

The Unger (6) modification of the syringe-cannula method consists of a simple device, a two way stop cock, by means of which the blood withdrawn into the syringe is switched into the vein of the recipient, and as the blood is being injected, a small stream of saline is thrown into the vein of the donor. When the reverse process takes place the saline is kept going into the vein of the recipient. The use of only one syringe for the blood was made feasible by a suggestion of Elsberg, that a constant spray of ether upon the syringe would prevent the expansion of the plunger and thus clogging the syringe. This method is simple, certain, and within the reach technically of any one possessing a knowledge of surgical cleanliness. Another device for accomplishing transfusion is the Kimpton (9) tube, which consists of a paraffined container in which the blood is collected from the donor and transferred to the recipient. The preparation of the tube is troublesome, the tubes are fragile, yet while the method seems cumbersome, it has a considerable following. Compared with the syringe method, it lacks ease of preparation, a large quantity of blood is drawn at one time, and if failure does occur much more is lost. The syringe method of transfusion with its present modifications has so simplified the matter that it is safe to say that it will supersede all other methods, except possibly those in which some chemical is added to the blood to prevent clotting during the transfusion.

The transfusion of blood being based upon the essential condition of its fluidity, efforts have been made to prevent clotting by the addition of chemical anticoagulants. Hirudin (leech extract) was tried, but was uncertain in action and often toxic when used in sufficient quantities to permit transfusion. Then followed the introduction of the citrate method of Lewissohn and Weil. With the addition of sodium citrate in proportion as low as 0.2 per cent. to the blood as it is withdrawn from the donor, it remains in a fluid state so that it may be given to the recipient at some later time, and this may be accomplished with a gravity syringe such as a salvarsan outfit. Lewissohn (7) showed by experiment that 0.2 per cent. of citrate was sufficient to accomplish this, and that as much as 1,000 c. c. of blood could be transfused by his method without producing toxic by effects. This innovation is of considerable import, and if certain objections are overcome it will, owing to its simplicity and availability, become generally adopted.

"Whatever the mode of action of citrated blood in transfusion, it is evident," say Satterlee and Hooker (8), "that when the citrate ion-concentration is sufficient to induce permanent incoagulability *in vitro*, the physicochemical effect in the circulation of the recipient must be considerable, and this effect probably varies in direct ratio with the amount of citrated blood introduced." They have devised a complicated (compared to similar devices) pipette and cannula in which a minimal amount of citrate solution is used.

Before taking up the question of the best method now available for general use, it is necessary to go back to the biochemical conditions under which transfusion is advisable or indeed safely possible.

The present technical development of transfusion would certainly not have taken place had not the laboratory given us a fairly safe criterion of the compatibility of the blood of two individuals when mixed in the circulation of one of them. These tests are used to exclude the possibility of hemolysis and agglutination when the bloods are mixed. In the tests it is sought to establish that the blood cells of the patient are neither hemolysed nor agglutinated by the serum of the donor and vice versa. These tests are now available in all well equipped hospitals. Ottenberg and Kaliski, after extensive experi-

ence, state that the relation between the test tube hemolysis and intravascular hemolysis is close, and it seems likely that in all cases in which there is test tube hemolysis, some intravascular hemolysis occurs, and that febrile reaction and urticaria or other skin eruptions occur after about ten per cent. of transfusions, irrespective of hemolysis and agglutination, and are not due to fibrin ferment or to blood platelet destruction. This indicates that intravascular changes take place that are not appreciable and cannot be forestalled by our present laboratory methods. It seems reasonable to assume that these changes are less likely to occur when chemically unaltered blood is transfused by the most rapid method.

Of the purely physical methods, the Unger modification of the syringe-cannula fulfills the conditions and combines ease of operation and certainty of performance. In a personal communication, Doctor Unger says:

> After carefully looking over my statistics I find that in the seventy-five transfusions I have performed, none of the patients had a chill due to the tranfusion *per se*. In one case a chill occurred. This transfusion was performed at an outside hospital and no test for agglutination and hemolysis had been performed. The patient had definite symptoms and a chill resulted. This chill would undoubtedly have been avoided had the tests been done. I think this absence of chills is due to the fact that the blood is outside of the body a minimum period of time (five to ten seconds) and that no chemical alterations have occurred. In the seventy-five cases, six had a rise in temperature. The temperature ranged between 100° and 102° F.
>
> The simplicity of the technic I need not dwell upon. In its final analysis it amounts to putting a needle into the vein of the recipient, another into the vein of the donor, turning a stop cock, and working a piston of the syringe back and forth. Mine is the method of choice for the following reasons: 1. The technic is extremely simple; 2, the patient receives whole unaltered blood; 3, chills, vomiting, and collapse are absolutely foreign to this method; 4, the amount to be transfused can be determined during the transfusion. One is neither compelled to waste blood nor to give less than the patient can stand; 5, a larger transfusion can be performed than with blood to which anticoagulants have been added; 6, patients transfused with whole blood are affected favorably for a longer period of time than those transfused with blood to which anticoagulants have been added.

If it can be shown definitely that the addition of the citrate and the stirring of the blood as required in this method, no detrimental change takes place, and if also it can be proved that the rise in hemoglobin, which takes place immediately after a citrate transfusion, is held as well as when the transfusion is done by the other methods, it will have a wide range of usefulness. Lewissohn admits that at present the syringe transfusion has been made technically as easy as the citrate method, but holds that the two main advantages resting with the citrate method are "that the patient and donor are not in the same room and that it is impossible to infect the donor's blood by the recipient's."

Perhaps the greatest advantage of the simplified technic of transfusion, beside its ease of performance, is that it can be repeated without trouble, and it has been shown that repeated injections have a high therapeutic value in certain blood conditions.

The question of the quantity of the blood to be transfused can best be answered by considering the individual case, the weight and condition of the patient, and the pathological state for which the transfusion is being done: it will also depend on the weight of the donor and his condition as the transfusion progresses. These conditions limit the quantity to be transfused, so that as small quantities as from sixty c. c. in infants up to 1,500 c. c. in adults may be used.

The present methods, while admirable and adequate, are probably capable of further simplification, and as the field of usefulness is immense they are probably not final.[1]

HEREDITARY CHOREA.

Early History and Remarks Upon a Barely Mentioned Psychic Peculiarity Which May Accompany It.

By Clarence King, M. D.,
Franklinville, N. Y.
Former Attending Physician, Cattaraugus County Hospital.

Hereditary chorea, as its name implies, is a peculiar form of chorea which resists all efforts at treatment and which, it must be admitted, is little understood. Its recognition dates back nearly three quarters of a century, before which time, as well as during its early history, it was doubtless confounded with other diseases. Thirty years ago, I wrote an essay upon it, which was published in the New York Medical Journal, in 1885, giving the complete history of a family for four generations in which it was known to exist in seven persons. At that time, as I afterward learned, there were but five or six papers descriptive of the disease in all medical literature, only one of which I had ever seen.

The first mention of the disease we find in a letter written by Dr. H. O. Waters to Professor Dunglison, of Philadelphia, which was quoted in full by him in the first edition of his *Practice of Medicine*, 1842; while in his third edition, 1848, he mentioned still another paper on the disease—an inaugural thesis, like mine, by Dr. Charles R. Gorman. This paper, however, was never published, and the only knowledge we have of it is the one short quotation given by Dunglison suggesting "imitation." The next observer to describe the disease was Doctor Lyon, in the *American Medical Times*, 1863; while still later Doctor Huntington, of Pomeroy, Ohio, gave a lucid description of it as a part of a general paper on chorea in the *Medical and Surgical Reporter* of Philadelphia, 1872. The last named writer has, however, been referred to by many as the discoverer of the disease, and his name is often given to it. But by just what process of reasoning he or his champions can figure out his claims of priority when there were at least three writers ahead of him,

[1] An excellent paper on the whole subject of Blood Transfusion is one by Ottenberg and Libman, *American Journal of Medical Sciences*, July, 1915, cl, 1, p. 936.

two of whom admittedly had given excellent descriptions of the disease, it is hard to see. If full credit is denied Waters, it evidently belongs to, or at least must be shared with that gifted man and keen and observant writer, Doctor Dunglison, who snatched from oblivion the two first papers and gave them to the world. The attempt to throw discredit upon Doctor Waters because he was also a minister of the gospel and consequently of a somewhat "roving" type, as was the custom of the ministry of his time, is hardly a fair interpretation of justice. But clearly, Doctor Lyon, who preceded Huntington by about nine years, should be given credit for the first case reports and for firmly establishing the disease as a distinct clinical entity, as he gave histories to confirm abstract descriptions.

During the years from 1885 to 1900 there were numerous papers published in all parts of the world, but for the last ten or fifteen years little has been written. I published a second paper in 1886 (1) giving a second family, and still another paper in 1889 (2), adding some minor observations to the clinical picture as already known. But it must be acknowledged that no one has been able to enlarge much upon the description of the disease as given in the original communication of Doctor Waters.

Hereditary chorea presents some features which are decidedly unique in the domain of medicine, and consequently very interesting. All authors to the present time, so far as I know, agree that heredity is its greatest, if not its only cause, and that this heredity must be direct and immediate. With one or two exceptional cases, which by the way are open to some question, it seems to be a law of the disease that a single break in the line of heredity is sufficient forever to render immune all future posterity. The course of the disease, after it has once begun, is slow, progressive, and relentless—not a single case so far reported has been known to end in recovery. Mental deterioration is an almost constant accompaniment in the later stages, and suicidal tendencies are common. Other very interesting characteristics are the age at which it develops—almost uniformly between twenty-five and forty years—the inordinate appetite, and the tendency to assume exceptional poses, each patient being more or less peculiar to himself. So far the clinical history is surprisingly uniform and any marked variation in the above mentioned symptoms must at once throw doubt upon the accuracy of the observation or the correctness of the diagnosis. But as to the pathology of the disease, it is different, as in the few cases that have come to autopsy the greatest variety of lesions has been found. The only constant finding so far reported has been a low grade inflammatory process of limited area involving different portions of the brain or its membranes. But even this in some cases has been insignificant in amount and apparently inadequate to account for the symptoms during life.

In a more recent review of the literature of the disease and summary of its symptoms (3) I have called attention to an observation made by Waters which very strangely seems to have escaped the notice of all other writers. He stated that in one of his patients the movements ceased temporarily under the influence of all kinds of instrumental music, except that from a common jewsharp. I have also mentioned having seen a man with obvious, if not advanced chorea, or at least apparent choreic movements, upon whom the soft tones of a church organ had a remarkably quieting effect which lasted about an hour. I now wish to report another case for what it is worth, for unfortunately I have to give this second hand, as it dates back before my time, to near the period, in fact, of Waters' observations.

A few months ago I met a former friend who for upward of thirty-five years was the keeper and superintendent of the county almshouse and hospital, situated in my old home town. During most of this time either my father or I was the attending physician, my service under his administration being about six years. My acquaintance with him was therefore intimate, and I have the greatest confidence in his veracity and reliability. Speaking of old time patients he mentioned a man with St. Vitus's dance who was in the hospital when he was there as superintendent and who afterward died there. This patient, according to the testimony both of my friend and of his wife[1] who was a remarkably clear minded and intelligent woman, and who recalled the case even more distinctly than he did, was unable to walk, except with the greatest difficulty and with the help of assistants, on account of the choreic movements. But the music of a violin, strange as it may seem, would quiet those movements wonderfully, so much so and so promptly that it became a regular practice for a fellow patient to play a few strains of music before he attempted to eat his meals. At night, of course, after tossing for some time, the movements would quiet down as he went to sleep, but it was not uncommon for him to throw himself from bed, or nearly so, unless soothed by music.

To some it may appear almost inconceivable that these movements, wholly involuntary and uncontrollable except for a short time, should be influenced even to the slightest degree by such means as music. But who will deny the influence of the emotions upon certain functional or even mild structural diseases under favorable conditions and in specially impressionable persons? The soothing strains of music have been known to appease the wrath of demons and to quiet the fury of beasts. The mother's lullaby, as she gently rocks her infant child, helps to dispel its fear of goblins and wafts the tiny one back to dreamland; while the stirring strains of martial music animate the soldier who is rushing to his certain doom, to the performance of deeds of valor and acts of heroism. Why, then, should we be skeptical as to the influence of music upon the brain centres in other directions? May there not be an idiosyncrasy with some of these patients, by which pathological stimulation of nerve tracts leading to involuntary twitching of muscle fibres is interrupted or held back by psychic means for a time, or the inhibitory action of the sympathetic stimulated in the same way that intense fear or anger deadens pain? Cases such as

[1]These people are both alive and will verify all I have said in quoting them. The question of this patient having true "hereditary" chorea is immaterial, as the psychic influence would doubtless be the same in other forms of the adult disease.

these seem to prove the possibility and at least call for further study. I have no doubt that other observers can adduce many instances, if not of hereditary chorea, then of some other taxic or spasmodic disease in which music has shown a favorable influence. Possibly it may be made a more valuable therapeutic measure than has been generally supposed, if we will but try it, ranking with or even higher than suggestion or hypnotism.

GONORRHEA AND ITS COMPLICATIONS.

Treatment with the Atoxic Antigonococcus Vaccine of Nicolle and Blaizot.

By A. Hyman, M. D.,
New York,
Adjunct Surgeon, Mt. Sinai and Lebanon Hospitals; Chief of Genito-urinary Clinic, Mt. Sinai Hospital Dispensary.

At a meeting of the French Urological Association, in 1913, Nicolle and Blaizot, of the Pasteur Institute in Tunis, reported a series of 200 cases of gonorrhea and its complications treated with a new vaccine. By growing gonococci on special media, they were able to produce a sensitized vaccine, which was both toxic and stable. The exact method of preparation of the vaccine has not been described.

The results reported by these two authors were remarkable, the more so because they were most striking in the severe complications of gonorrhea. To summarize their conclusions: 1. Gonorrheal ophthalmia was cured after several inoculations, sometimes after one. 2. Orchitis—several hours, or at most a day after the injection, the pain ceases, fever disappears, and resolution commences; sterility was avoided in practically all of the cases. 3. Rheumatism—the symptoms and physical signs rapidly improved. In three cases cure followed two to eight injections given every two to three days. 4. Acute and chronic urethritis—a number of cases were cured after three to six injections.

This remarkable report was soon followed by the publications of many other French observers. In the main most of these reports substantiated the results of Nicolle and Blaizot. A few observers, however, reported negative results, and others asserted the vaccine to be untrustworthy. Murphy and Kreuschler (8), in an article upon vaccine therapy, cite the results obtained by Nicolle.

In 1914, I obtained a sufficient supply for the treatment of twenty-five cases. In view of the remarkable qualities attributed to this vaccine, I consider it of value to report the results that were obtained; first, a few words as to dose, method of injection, and reactions. For each injection 0.5 c. c. of vaccine, containing three billion bacteria, diluted with 1.5 c. c. of physiological salt solution, is given. The dose is not increased with subsequent injections. Injections are administered either intramuscularly or intravenously. The former were generally followed by severe pain at the site of inoculation of several hours' duration. There was usually no febrile reaction. Acute cases were inoculated every day or every other day; chronic cases every two to four days. Six to eight injections constitute the prescribed course of treatment. Untoward effects were never observed.

Nicolle and Blaizot employed urethral irrigations of potassium permanganate in most of their cases. In order to determine the efficacy of their vaccine the usual local treatment was withheld in most of the cases here reported. The only treatment for the acute complications was rest in bed. Some of the ambulatory cases were treated with potassium permanganate irrigations. Following is a summary of the series of cases treated with this vaccine.

Case I. F. C., male, twenty-five years old, March, 1914. Acute anterior posterior gonorrhea, four weeks' duration. Complications: Acute prostatitis, acute epididymitis. Local treatment: None during stage of complications. Vaccine treatment: Eight intramuscular injections. Relief of pain in epididymis after second injection; gonococci still present at end of treatment. Prostate and epididymis somewhat improved. Result unsatisfactory.

Case II. A. C., twenty-four years old, February, 1914. Acute anterior gonorrheal urethritis, one weeks' duration. Local treatment: Irrigations of potassium permanganate daily. Vaccine treatment: Nine intramuscular injections, one every other day. Discharge ceased after fifth injection. Three days after cessation of treatment, recurrence of discharge with gonococci. Result unsatisfactory.

Case III. A. M., twenty-five years old, March, 1914. Chronic prostatis, three months' duration. Gonococci present in prostatic secretion. Local treatment: Intravesical irigations of potassium permanganate. Vaccine treatment: Eight injections, one every third day. Discharge very scant, gonococci still present. Urine clearer, contained fewer shreds. Results unsatisfactory.

Case IV. G. N., twenty-nine years old, May, 1914. Chronic prostatitis, two and a half months' duration. Gonococci present in discharge. Complained of rheumatic pains in knees and elbow joints. Local treatment, none. Vaccine treatment: Six intramuscular injections, one every third day. After fifth injection, gonococci disappeared. No recurrence when seen two months later. Cultures negative. Result excellent.

Case V. L. M., twenty-eight years old, July, 1915. Chronic anterior and posterior urethritis; chronic prostatitis; gonococci present in culture. Gonococcus complement fixation test positive. Local treatment, none. Vaccine treatment: Eight injections, one every third day. After eight injections cultures were negative for gonococci; prostatic condition considerably improved. Complement fixation, one month later, positive. Result good.

Case VI. E. S., twenty-six years old, June, 1914. Chronic anterior posterior gonorrheal urethritis; chronic prostatis recurrent, few years' duration, gonococci present. Local treatment: Potassium permanganate, intravesical irrigations. Vaccine treatment: Eight injections, one every third day. Disappearance of gonococci during course of treatment, recurrence of discharge with gonococci few days after last injection. Result unsatisfactory.

Case VII. J. M., thirty-five years old, June, 1914. Chronic prostatitis, stricture of urethra, acute exacerbations with acute epididymitis. Gonococci present in discharge. Local treatment: Anterior irrigations with potassium permanganate. Vaccine treatment: Eight intramuscular injections, one every other day. Discharge still present, with gonococcus. Complement fixation test. Result unsatisfactory.

Case VIII. E. S., twenty-one years old, April, 1914. Acute anterior posterior gonorrhea, acute prostatis, acute bilateral epididymitis, one week's duration. Local treatment, in bed, cold applications to testes. Vaccine treatment: Eight intramuscular injections, one every other day. After seventh injection discharge diminished considerably. Epididymides smaller and painless after third injection. Prostate much smaller. No gonococci found; no recurrence two months later. Result good.

Case IX. H. K., twenty-one years old, January, 1914. Chronic anterior posterior urethritis, chronic prostatitis, one year's duration. Recurrence of discharge with gono-

cocci when treatment was discontinued for few days. Local treatment, none. Vaccine treatment: Eight intramuscular injections, one every third day. Discharge ceased after fourth injection; no gonococci present. No recurrence when seen one month later. Cultures negative. Result excellent.

Case X. A. R., twenty-four years old, June, 1914. Acute anterior posterior gonorrhea, acute prostatitis, three months' duration. Discharge with gonococci. Local treatment, none. Vaccine treatment: Eight intramuscular injections, one every other day. After fifth injection discharge ceased; cultures of prostatic secretion after eighth injection showed gonococci. Result unsatisfactory.

Case XI. H. K., twenty-four years old, September, 1914. Acute anterior posterior gonorrhea, acute prostatitis, acute epididymitis, two weeks' duration. Local treatment, none. Rest in bed. Vaccine treatment: Eight intramuscular injections, one every other day. Gonococci still present; discharge diminished somewhat. Prostate enlarged and contained much pus. Epididymis smaller, not painful. Result unsatisfactory.

Case XII. D. K., thirty years old, October, 1914. Acute anterior posterior gonorrhea, acute prostatitis, three weeks' duration. Local treatment, none, while vaccines were being given. Vaccine treatment: Eight injections, one every other day. Discharge diminished somewhat, prostate slightly smaller; gonococci still present. Result unsatisfactory.

Case XIII. S. H., twenty-two years old, August, 1915. Acute anterior posterior gonorrhea, acute epididymitis, three weeks' duration. Local treatment: Rest in bed, cold applications. Vaccine treatment: Eight intramuscular injections. Discharge still present, gonococci present, epididymus still large and painful. Prostate enlarged and contained much pus. Result unsatisfactory.

Case XIV. J. B., twenty-nine years old, March, 1915. Chronic anterior posterior gonorrhea, chronic prostatitis, three years' duration, with a few acute exacerbations. Present attack of three months' duration, gonococci present. Local treatment: Anterior irrigations of potassium permanganate. Vaccine treatment: Intramuscular injections every third day. After sixth injection, cessation of discharge. Prostatic secretion contained less pus. Free from discharge for three months, then recurrence after coitus. In this case it was impossible to decide definitely whether the recurrence was due to a new infection or to the lighting up of an old process. Result satisfactory.

Case XV. I. K., July, 1914. Infection of prostate; prostatectomy three months previously; marked swelling of left ankle (gonorrheal arthritis?), temperature 103° to 104° F., painful joints for several weeks; two sinuses in perineum through which pus exuded. Left epididymus enlarged and hard. Local treatment, none. Vaccine treatment: Seven injections. Rapid disappearance of symptoms in the ankle. Diminution of pus from the sinus in the perineum, gradual improvement, so that patient was able to walk again within three or four weeks. Result satisfactory.

Case XVI. I. W. Chronic prostatitis. Local treatment, none. Vaccine treatment: Six injections. Some improvement, but not striking. Result unsatisfactory.

Cases XVII, XVIII, XIX. Gonorrheal infection. Local treatment, none. Vaccine treatment: Six injections each. These cases showed some improvement, but not more than was regularly noticed in other types of treatment. Result unsatisfactory.

Case XX. D. I., eighteen years old. Acute pyosalpinx, acute urethritis, gonorrheal rheumatism involving ankle and wrist joints. Gonococci in smears. Local treatment, none. Vaccine treatment: Eight injections, one every other day. After fourth injection diminution of swelling and pain in joints—this was quite marked—but a few days after injection recurrence of pain, swelling, and fever. Urethritis and pyosalpinx uninfluenced. Result unsatisfactory.

Case XXI. Chronic prostatitis and seminal vesiculitis, ten years' duration, with numerous recurrences. Time of injection severe anterior posterior infection—no gonococci found. Urine cloudy with shreds. Complement fixation test positive. Vaccine treatment: Six injections. Condition about same. Result unsatisfactory.

Case XXII. A. W., thirty years old, July, 1914. Acute anterior gonorrheal urethritis, three weeks' duration. Local treatment: Potassium permanganate anterior irrigations. Vaccine treatment: Six injections. Gonococci still present after last injection. Result unsatisfactory.

Case XXIII. E. S., twenty-six years old, August, 1914. Acute anterior gonorrheal urethritis, one weeks' duration. Local treatment: Potassium permanganate anterior irrigations. Vaccine treatment: Seven injections. Gonococci present after last injection. Result unsatisfactory.

Case XXIV. A. S., twenty years old, August, 1914. Acute anterior posterior gonorrheal urethritis, acute prostatitis. Local treatment, none. Rest in bed. Vaccine treatment: Eight intramuscular injections. Gonococci present in prostatic secretion after last injection. Result unsatisfactory.

Case XXV. A. K., aged twenty-six years, June, 1914. Chronic gonorrheal prostatitis of many years' duration. Gonorrheal arthritis of knee joint with numerous acute exacerbations. Fluid in joint. Local treatment: Knee in splints. Vaccine treatment: Six injections. Marked improvement, pain and swelling disappeared, recurrence one year after. Result satisfactory.

SUMMARY.

A series of twenty-five cases of gonorrhea and its complications was treated with the vaccine of Nicolle and Blaizot. During the period of vaccine treatment local therapy was withheld. Most of the cases had one or more complications at the time the treatment was administered. Seven (twenty-eight per cent.) were definitely cured by the vaccine; of these, two were brilliant results (Cases VIII-IX). Cases of uncomplicated acute and chronic urethritis were not influenced by the treatment. Cases of epididymitis were only slightly improved. Cases of chronic prostatitis showed the highest percentage of cures. Rather marked improvement followed the treatment in a few cases of gonorrheal rheumatism. Temporary improvement was often noticed during the course of treatment, to be followed by recurrences when the treatment was discontinued. The gonococcus complement fixation test was not influenced in any of the cases. The vaccine was found to be innocuous; toxic symptoms never developed.

As a result of these experiences, it must be concluded that the atoxic gonococcus vaccine, although occasionally followed by a brilliant result, is most inconstant in its effects. It cannot be relied upon for a satisfactory result in any given case. It is conceivable that this vaccine may be modified so that more constant effects may be expected. The results in some of the cases justify further experimentation with the vaccine of Nicolle and Blaizot.

The percentage of cures in my series of cases was no higher than that obtained with the usual methods of treatment at our disposal.

I wish to express my indebtedness to Dr. M. Kakels, of New York, through whose kindness the vaccines were obtained, and to Dr. Edwin Beer, who kindly turned over to me vaccines that had been placed in his hands. Of the reported cases several were treated by Doctor Buerger, Doctor Kakels, and Doctor Kaliski, of this city, and one by Doctor Simons, of Nashville, Tennessee. I wish to thank these gentlemen for their case reports.

Our Readers' Monthly Prize Discussions

Twenty-Five Dollars Is Awarded for the Most Satisfactory Paper

All persons, whether subscribers or not, are invited to compete for the prize of $25 offered for the reply deemed best by the editors to the following questions:

CLXXII.—What are your methods of resuscitation and aftercare of persons apparently drowned? (Closed.)

CLXXIII.—How do you perform circumcision? (Answers due not later than August 15th.)

CLXXIV.—How do you treat ivy poisoning? (Answers due not later than September 15th.)

The award will be based solely on the value of the information contained in the answer. No importance will be attached to literary style. Answers should preferably contain not more than six hundred words, and should be written on one side of the paper only. All papers submitted become the property of the JOURNAL, and should bear the full name and address of the author for publication. The prize will not be awarded to the same person more than once within a year.

The prize of $25 for the best answer to Question CLXXI was awarded to Dr. Lionel C. Charbonneau, of Brooklyn, New York, whose paper appeared on page 265.

PRIZE QUESTION NO. CLXXI.

THE TREATMENT OF SPRAINED ANKLE.

(*Continued from page 268.*)

Dr. Charles C. Hewin, of Springfield, Mass., holds that:

The treatment of a sprained ankle may be divided as follows: 1. Sprain of a slight degree, where there is little pain and tenderness and little swelling, especially below the external malleolus. For the first and second day following the injury the limb should be kept in a horizontal position and treated by hot fomentations, light massage, and passive motions two or three times a day. On the third day and thereafter it should have a hot douche for about thirty minutes, followed by a cold douche for one minute, and followed by massage. Another plan is to apply adhesive strapping at once.

2. A sprain of medium severity, where the pain and tenderness are more marked, the swelling is greater and involves the whole circumference of the ankle, there is difficulty in walking, and some of the ligaments are ruptured: After the preliminary treatment with hot water, or hot fomentations and massage, adhesive straps should be applied to the foot, ankle, and leg. They serve a threefold purpose, keeping the foot in a correct position, preventing extreme motion in any direction, and exerting automatic massage by varying the pressure in different parts every time the foot is moved. The leg should be shaved, washed with soap and hot water, alcohol, and ether. Strips of adhesive plaster should be applied in such a manner as to fit accurately, and each will overlap the next by a third of an inch. A good plan is to apply a broad strip like a stirrup, extending from below the knee on the inner side of the leg, covering the inner malleolus, the plantar surface of the heel, the outer malleolus, and finishing on the outer surface of the leg near the head of the fibula. A light gauze bandage completes the dressing. On the third day the patient can walk about with a cane, but the massage and passive motion should be continued. After about two weeks it may be removed; but douches and massage should then be resumed and continued as long as the joint is weak.

3. In sprains of extreme severity, there is great pain and swelling, and much abnormal motion amounting to a partial dislocation. We often suspect a fracture of the malleolus, but it is impossible to prove without a radiographic examination. The plan of treatment is as follows: We should elevate the limb and apply hot fomentations to relieve the pain, and keep them hot with hot water bags. The limb should be fixed by sandbags. Two or three times a day, the dressing should be removed and gentle massage given. On the third or fourth day, when the swelling has somewhat subsided, the leg should be shaved, covered with sheet wadding, and encased in a plaster of Paris bandage from the toes to the knee, the foot being held at a right angle. After two weeks the cast should be removed, a hot douche and massage should be given twice a day, and passive and active motion begun.

Dr. Solomon Weingrad, of Mountaindale, N. Y., directs:

Order the patient to immerse the foot in a basin of warm water and adding gradually hot water until the patient can stand the heat without discomfort on his part, keep foot in the water for fifteen minutes. Afterward dry the foot thoroughly and cover with flannel or other material at hand. Repeat same maneuvre four times at three hours' interval.

Order patient not to step on foot for twelve hours after the last foot bath.

If the case is seen late, a day after injury, where there is swelling and painful motion, reduce swelling with cold applications and bathing with liquor Burowi. After swelling has been reduced, apply a light cast from above the ankle to the toes; keep this on for a week, remove same, and order massage from below upward, and passive motion for about a week before the patient is allowed to walk.

Dr. William J. Ryan, of Philadelphia, suggests:

First ascertain whether the injury is external or internal—sprains of the external lateral ligament are most common. After diagnosing a sprain, apply a gauze dressing soaked in magnesium sulphate in a saturated solution, or some other evaporating lotion. Then, if such a thing is handy, place the injured member in a fracture box, which should be padded with a small pillow. An oiled silk or wax

paper cover over the dressing prevents rapid evaporation. If not, place the foot and leg on a small thin pillow and strap the pillow on with buckled straps of canvas, or with a wide bandage. Straight internal and external lateral splints outside the pillow are most important in preventing motion. If a pillow cannot be had, a folded sheet or a couple of towels make an excellent padding for the splints.

Usually in about forty-eight hours the swelling has subsided sufficiently under this treatment to permit of more careful examination. If at all doubtful as to the presence or absence of fracture, by all means resort to the x ray. At this time the extent of lateral mobility can be easily determined. If there is none and only a point of tenderness and some pain on bearing the weight of the body are found, an adhesive boot may be applied and is as simple and efficacious as any other dressing. This may remain on a week, after which it can be removed, and a few hot baths for the foot followed by an alcohol rub will suffice.

If there is excessive lateral motion, it means a complete or nearly complete ligamentous tear, or a sprain fracture. In either case a plaster of Paris or a sodium silicate cast may be applied, with the foot in slight inversion or reversion, depending directly on which side the tear has occurred, always having the long axis of the foot at right angles with the long axis of the leg. The cast may be made to cover only the posterior half of the leg and ankle and the bottom half of the foot; this permits of inspection without removing the cast.

This cast should remain on for three weeks. When it is removed, massage and passive motion are in order, and between treatments a firm bandage should be worn. Walking should be at first with two crutches, then a crutch and cane, and so on until the full weight can be borne.

I have never had to resort to narcotics for pain in any case, although in nervous individuals and alcoholics sedatives are indicated.

Dr. Gustavus Eliot, of New Haven, Conn., points out that:

The two most important factors in the treatment of a sprained ankle are rest and pressure. The necessity for thorough use of these therapeutic agents depends upon the severity of the injury to the structures; the extent of this injury it is impossible to determine exactly; it is probable that it varies from a slight stretching of one or more of the ligaments and tendons about the joint, to extensive laceration and bruising of the tissues.

These injuries are accompanied by pain, swelling, and impairment of function. If the sprain is slight, consisting of a moderate sudden stretching of a ligament, acompanied by transient pain, a brief rest with careful resumption of the use of the joint may be sufficient.

If the injury is a little more severe, so that pain persists, and there is slight impairment of function when the joint is used, accompanied by slight swelling, the application, with gentle friction upward, of an evaporating lotion will assist in restoring the joint to a normal condition. An old but useful mixture is:

℞ Ammonii chloridi, ...3iv;
Alcoholis, ...3iv;
Aquæ, ...q. s. ad 3viij.
M. Sig. Shake. Apply externally every two hours.

If the injury is severe, so that there is much pain, considerable swelling, and great impairment of ability to use the affected limb, the patient should be placed in bed; the foot, ankle, and leg should be massaged gently but firmly from the toes toward the knees, so as to diminish the swelling, if possible. An anodyne and stimulating application may advantageously be used with the massage. Another ancient but useful formula is one recommended by Hahnestock before the middle of the last century:

℞ Olei origani, ...
Tincturæ opii, ...
Spiritus ammoniæ, } .....āā 3i.
Olei olivæ, ...
M. Sig. Warm a small amount and apply with gentle friction.

This should be thoroughly rubbed into the skin; do not apply cloths soaked with it. The joint should then be enveloped with absorbent cotton which has been warmed, the foot and ankle should be evenly and firmly covered with a flannel or cotton bandage, and the limb placed in an elevated position. The dressing should be reapplied every day, the joint thoroughly rubbed with the liniment, the cotton heated, and the bandage reapplied. The patient should not be allowed to use the affected part so long as effort causes pain.

In cases which have not been properly treated at the beginning, and in acute cases in which the pain and swelling have subsided, the method of treatment popularized in this country by Dr. Virgil P. Gibney, of New York, is exceedingly useful. The limb is elevated, and massaged firmly from the toes toward the knee. The ankle and foot are then enveloped with strips of adhesive plaster: the first resting on the bottom of the heel, the two ends passing upward back of and above the malleoli; the next resting on the back of the heel, the two ends passing forward under the malleoli to the bases of the great and small toes. These are succeeded by other strips, alternately vertical and horizontal, until the entire foot, ankle, and three inches of the lower end of the leg are firmly encased with strips of adhesive plaster. A layer of absorbent cotton may with advantage be placed over this, and the whole covered with a cotton bandage. As the joint improves, the cotton may be dispensed with, and later the bandage, leaving the adhesive plaster until the joint is restored or a new dressing is needed.

Dr. Frank C. Makepeace, of New York, points out that:

The treatment is divided into three stages, viz., immediate treatment, secondary treatment, and aftertreatment.

Immediate treatment: The patient is placed in bed, with the injured leg in a horizontal position and supported by a soft pillow, and an ice bag applied constantly for a few days until the pain becomes less severe and the swelling is somewhat reduced. During this period he must not use the injured member.

Secondary treatment: When the swelling has

been somewhat reduced and the pain lessened in severity, the injured ankle is strapped with adhesive plaster about one and one half inch wide; these strips overlap each other like a figure of eight bandage and extend from a short distance above the joint entirely around the plantar surface of the foot, so as to enclose the entire ankle joint. The patient is now permitted to walk on the injured member, but will probably have to have the assistance of a cane for about a week or ten days.

Aftertreatment: After the expiration of about two weeks, the time depending on the disappearance of swelling and pain, the straps are removed and the injured joint is gently but thoroughly massaged daily. The patient is now permitted to use the ankle freely, but he should be instructed to be careful not to injure it by overexertion. It is also a good plan to advise the wearing of an ankle brace, bandage, or other appliance, during working hours for several weeks.

If the ankle should become swollen or unusually painful during the aftertreatment, the adhesive strapping may again be employed and allowed to remain in place for a week or ten days.

Dr. Leo Faske, of Brooklyn, New York, states:

As we all know, sprains are divided into three classes according to the severity of the sprain, and our treatment must be for the three classes or divisions accordingly.

The treatment of the first class, where the pain and tenderness are not severe, and there is little swelling, and patient can use the foot with little discomfort—is to keep the foot at rest and apply heat or cold. I get good results from lead and opium wash and also from Burrow's solution. I apply a firm gauze bandage to the foot and saturate it with the solutions, and then keep an ice bag on the wet bandage. This type of cases usually terminate favorably in two or three days. If the cold does not relieve, I apply hot fomentations for a while. I allow this type of patient to walk on the third day. Here adhesive strips, applied so as to form a sandal on the foot, help a great deal.

If there is no improvement shown at the end of the third day, I proceed with the treatment of the second class. In the second class I apply a flannel bandage to the ankle, beginning at the toes and working up to about four inches above the joint; then place the foot in water, which should be very warm, for an hour or two. This treatment sometimes stops the swelling. After this, I apply my adhesive strips in the Blaisdell fashion. I first shave the lower limb if it is very hairy. The strips of adhesive plaster should include the leg, the ankle, and the foot. My first strip is a broad one, being about one and one half inch wide, beginning at the inside of the leg, about four inches below the knee, keeping the foot at a right angle to the leg, covers the inner malleolus, the plantar surface of the heel, the outer malleolus, and ends on the outer side of the leg about four inches below the knee.

This is my main strip; it reenforces the lateral ligaments of the joint, which are usually stretched or torn. When the foot is at right angles to the leg, it relaxes the ligaments, and my first strip is utilized at a great advantage.

Another strip about one inch wide is passed around the leg about one and one half inch above the joint, and still another about three inches above the joint; these two strips hold my first strip in place and make the leg firm.

If you want to avoid any swelling of the leg or foot which may be due to these strips, don't bring them entirely around the leg. The other strips are placed, one at a time; the centre of each strip is placed on the plantar surface of the foot and the ends cross each other on the dorsal surface of the foot in front of the joint and are attached to the sides of the leg above the joint. These strips should be about three quarters of an inch wide and should overlap about one quarter inch and form a perfect sandal, until almost the entire foot, ankle, and lower part of the leg are encased, excluding the toes and about two inches of the foot anteriorly.

On top of the adhesive plaster dressing I apply a gauze bandage and an ice bag. Massaging the foot several times a day does good.

Never allow the patient to walk for at least five or six days. The adhesive plaster should be left intact for ten days, then removed. To remove the adhesive plaster without pain, pour benzin on the plaster and you can easily peel it off; hot and cold douches and massaging of the foot help a great deal.

Elderly people do not seem to stand the cold applications well, therefore try them with the heat first, and then change, if necessary.

In the third class, I always insist on an x ray picture being taken. The foot should be firmly bandaged and hot fomentations applied. We may also use lead and opium warm, or Burow's solution. On top of the wet dressing, keep a hot water bag so that the heat may be maintained. This relieves the pain as well as the swelling.

The dressing may be removed at times in order to massage the foot. When the swelling has subsided somewhat, apply a plaster of Paris bandage and keep it on for at least three weeks. In applying this bandage, have the foot at a right angle to the leg.

After recovery from a sprained ankle, have the patient wear an anklet so as to prevent recurrence in the same joint, which is weakened from the first sprain. If pain is very severe, I resort to codeine, morphine sulphate or Dover's powder. After the acute symptoms have subsided, I massage with stimulating liniments and apply a tight bandage.

In gouty and rheumatic individuals, look out for ankylosis of the joint. In elderly patients I give the iodides, especially potassium, and tonics if the stiffness is marked.

(*To be concluded.*)

Case of Multiple Cartilaginous Exostosis.—H. W. Marshall (*American Journal of Orthopedic Surgery*, June, 1916) reports a case of multiple osteochondromata. Numerous photographs and x rays show growth on many bones of the body. An examination of one of the growths showed it to be benign in character. There was a significant family history in this particular case.

Food and Food Preparation, in Health and Disease

FOOD, DRUGS, AND LONGEVITY.

Some Thoughts on Their Relations,

By Leroy D. Swingle, Ph. D.,
Department of Pharmacology, University of Utah.

(*Continued from page 172.*)

The possible effects of drugs on the germplasm and through it upon the length of life of the soma of the following generations, have not received sufficient consideration. The reason for this probably lies in the facts that the manifestation of any change in the germplasm must be delayed till future generations appear, and that the attention is naturally directed toward the relief of the suffering somatoplasm. All sorts of active drugs are administered, with very little thought as to what effect they may have on the life of the following generations. In the case of the soma, sooner or later, a howl is set up if a deleterious action occurs, but with the germplasm the symptoms are delayed till the next generation, or possibly for several generations, before full effects can be observed. Neither the microscope nor chemical reactions reveal the undifferentiated, specific characters that are bound up in a germcell. Much less, then, will they reveal the slight changes that drugs may produce in those characters. It is only by looking backward through the functions and structure of the somatoplasm unfolded from that germcell that we are able to determine what changes drug therapy is producing in the germplasm. The future generations may rise up and curse us for the attempts we have made to prolong the life of the somatoplasm of this generation, without first considering the possibility of bringing through the medium of the sex cells a curse upon the somatoplasm of the following generations. A fool can injure the germ cells, while the wisest man cannot mend them. In this connection we also ask what effect will the inhalation of the noxious fumes generated in our modern manufacturing plants have upon the life of our progeny?

I fancy that at this point I may be charged with defending the doctrine of the "transmission of acquired characters"; but not so. Well I recognize that the property of stability has been wisely placed in the germplasm, while equally wisely the properties of variability and adaptability have been given the somatoplasm. Were this not so, were the properties reversed, the somatoplasm exposed to varying conditions would not be able to live long enough to reach sexual maturity, while the germplasm by that time would be so deranged that nothing but monstrosities could be produced, and death would overtake both in a few years. Nevertheless, though the germplasm is comparatively stable, there is definite proof that it may be altered by food and drugs. As a result of Weismann's scholarly and effective attack on the doctrine that acquired characters may be transmitted, and on account of the confirmation of his view by modern experiment, there may result a failure on the part of medical men to appreciate the truth of the statement that food and drugs may affect the germplasm. Let it not be thought that the admission of the truth of this statement is an acceptance of the idea that acquired characters may be transmitted. This doctrine has to do with the evolution of organisms by the transmission to the offspring of a character, positive or negative, which has been acquired by the somatoplasm of the parent. It will be seen that this requires that the addition of a character to, or the removal of a character from the somatoplasm of the parent shall so modify the potential relations in the germcells that these very characters will unfold in the embryo of the offspring and will be exhibited by its somatoplasm during some stage in its life. It is needless to say that such a modification of the germplasm would doubtless manifest itself in the generations to follow. To illustrate, suppose that in a salamander, independent of the characters of its parents, should develop an abnormally broad head and heavy jaw as a result of special environmental or food conditions, and further suppose that these same characters should appear in its offspring which is raised under normal environmental and food conditions; this would be a case of the transmission of acquired characters. The first supposition need not be made, for such characters are actually acquired under the conditions mentioned (Powers, 5). Many other similar cases could be mentioned, but in no case is there any tendency for the characters to appear in the offspring. So not only reason but also experiment teach us that acquired characters are not transmitted. Fortunately nature is as wise as the biologist and has purposely determined that acquired characters shall not be transmitted. We cannot imagine the transmission through the germcells of an acquired character, whether it is an addition to, an injury, an atrophy, or an hypertrophy of the somatoplasm, to the offspring, so that such a condition will appear in a corresponding or, for that matter, in a different part of the offspring. But this is what is comprehended in the evolutionary doctrine of the transmission of acquired characters. Yet, on the other hand, we can conceive, in fact would expect *a priori*, that any injury to the germplasm itself would be manifested in some definite defect or a more general weakness of the somatoplasm of the offspring. In the lower animals if direct violence is done to the germ cells to the proper degree, the offspring may lack parts, or present anomalies, or fail to develop completely. We reason that, since from our present knowledge of the cytology and chemistry of the germplasm, it cannot be determined what shape the parts of the offspring will have, or in fact it cannot even be determined whether certain structures will be present at all, it is possible that various unobservable derangements of the germplasm may slowly result from its contact in the body with improper nutrient media or with drugs administered therapeutically,

or with poisons taken accidentally or as beverages. It could hardly be conceived that such conditions would ever add any new and valuable characters to the germcell—the most complex mass of structural and physiological potentialities. It would be too much like attempting to improve a delicate watch by going after it with hammer and anvil.

There is much evidence that alcohol—a food, a beverage, a drug, a poison—has a direct action on the germcells and through them on the anatomical structure and physiological processes of the progeny, impairing its health and shortening its life. All are familiar with the deleterious effects on the soma of an excessive use of alcohol and with the fact that the life may be shortened thereby. But recent experiments by Stockard (6), of Cornell Medical College, on the guineapig, where alcohol was given in daily doses, show that the germplasm may be profoundly affected. Offspring from such pigs showed a higher mortality, more deformity and sterility, paralysis, absence of eyes, etc. Moreover, the great grandchildren showed the greatest defects, although none but the great grandparents received alcohol. Thus, the effects were cumulative. The effects on longevity are manifested in the fact that many of the offspring were early abortions, many were stillbirths, and many died soon after birth. The amount of alcohol given, although too small to have any effect upon the length of life of the generation receiving it, produced an extreme effect upon the germplasm. We should expect smaller doses given over many generations to produce, though more slowly, similar results.

Beside these experimental evidences of the deleterious effects of alcohol through the germplasm upon the soma of the progeny, there are confirmatory observations upon the families of drunkards. It may be suggested, therefore, that ever since Noah disgraced the human family, there has been a progressive degeneration of the race, and chiefly as a result of the almost universal use of alcohol as a beverage, a food, a drug. It is doubtful whether any of us can boast of a lineage free from its hereditary contamination. Had no alcohol been used, other things remaining the same, we believe that the preceding data suggest the conclusion that the race at present would be stronger, longer lived, and less defective, especially in respect to the nervous system.

Therefore, we ask, How much effect is the amount of alcohol that is being administered in patent medicines and in other prescriptions having upon the somatoplasm of future generations? Another question may also be asked: What effect will our modern drug therapy in general have upon the life of future generations? Granted that the barrels of medicine that are being swallowed have a beneficial effect on the soma of the present generation, can we be sure that the future generations will not suffer more than the present gains? It is easier to injure the germplasm than to mend it. For the former, knowledge is not required, but certainly ignorance (and what a supply!) can never accomplish the latter. Some toxins and drugs, other than alcohol, have been proved to injure the germ cells. Should we not, therefore, consider the possibility that in attempting to prolong the life of the present individual, before and during the period of procreation, by the use of drugs, the lives of their progeny may be irredeemably shortened? On the other hand, biological and dietetic treatment and prophylaxis for prolonging the life are lines along which medicine may develop without endangering the race. In fact, these measures, instead of having in themselves a deleterious effect upon the germplasm, may check its tendency to derangement by removing the exciting causes such as poisons resulting from infections and from food decomposition, etc. Metchnikoff has gone so far as to suggest that the poisonous products of putrefaction in the digestive tract are the causes of old age and death. Well may these poisons be contributing causes, though Metchnikoff's view is extreme, and if they are, they would probably contribute in a measure to the derangement and senility of the germplasm as well. Treatment and prophylaxis in the form of dietetics, immunization, and possibly even psychotherapy, ought to do much for the life of the present individual and toward the preservation or increase of the longevity of the progeny. Profound changes are known to be brought about in the somatoplasm of animals from various levels in the phylogenetic series, by varying the food conditions; as examples, we may mention the protozoa, the hydra, the rotifers, insects, salamanders, and even man. Of course these changes in the soma are not transmitted to the offspring, but there may be nevertheless certain obscure effects upon the germplasm that have not been determined.

There is some evidence that man in the dawn of history lived to be much older than at present, and also that there has been an impairment in his mental capacity. This is the equivalent of an admission of an organic degeneration in man, an idea which is not generally entertained in modern literature. It is not within the province of this communication to present the evidence for and against this idea. Yet it is patent that the line of argument presented in this treatise leads to such an idea. We have stated or implied that unfavorable environment and food have necessitated a struggle for existence and that in the struggle the fittest have naturally tended to survive. Yet there is nothing, as far as we can see, in struggle for existence and its consequent natural selection, that can raise the race above the best in the race, but on the other hand, if conditions are such as to necessitate a struggle on the part of the protoplasm in order to maintain its existence at all, the protoplasm would tend to be injured by that environment rather than improved. Geology seems to bear testimony in favor of this idea. It is apparent that no somatoplasm escapes injury while in contact with its environment. It has been indicated that bad food conditions and poisons such as alcohol may injure the germplasm, and to such conditions the human race has been quite universally subjected for thousands of years. These alone have, therefore, constituted sufficient cause for the degeneration of the race. We are aware that few will admit the truth of this statement; but many will not admit it because they confound organic change with another quite differ-

ent matter, namely, the products of the race—its knowledge, its scientific achievements, its customs, its social relations and institutions. The possible fact that the race may have experienced organic degeneration, does not oppose the fact, which all admit, that there has been an upward evolution as respects some of these other matters. It must be remembered that the race today has had at least 5,000 years more time in which to develop and accumulate these things than the race had had at the dawn of history. No one would think of attributing the modern developments, which mark the present age, to a recent upward organic evolution of the race, manifesting itself in a mental brilliance. We ask, Where would the race be now, were it not for its organic degeneration, which has been opposing to some extent the growth or evolution of these other things?

In closing, we reiterate that theoretically an increase in the length of life of the somatoplasm, and as a concomitant to it, an increase in human happiness, which after all is the *summum bonum* for man, must come through three avenues: 1. The development, if possible, of a more perfect organism through the means suggested by eugenics; 2, the improvement of the environment both of the somatoplasm and also the germplasm, which, though comparatively stable, has been proved to be susceptible to poisons circulating in the blood which constitutes its environment; and, 3, the determination of what would constitute a more nearly perfect diet and the application of it in prophylaxis and therapeutics. The best results may be expected along the last two lines.

Dietetic Food Values.—In a study on food and the food value of the dietary at the New York City Municipal Sanitarium, carried out by Robert J. Wilson and Walter L. Rathbun, the following conclusions were reached: 1. Food studies should be carried on at regular intervals and the records should be made available for comparative purposes; 2, the elimination of meats and eggs from the morning meal and the substitution of milk is a sound and justifiable economy; 3, the dietary of the tuberculous should be high in caloric value, but should be confined to three daily meals in all but exceptional cases; 4, males consume more food than females both in total amount and in number of calories to the pound of body weight, but females make larger gains; 5, the avoidance of frequent repetition of foodstuffs is desirable; 6, small initial servings with as many "seconds" as may be desired is satisfactory to the patients and prevents much plate waste.

Maple Syrup.—According to the *Quarterly Bulletin* of the State Board of Health of New Hampshire for April, 1916, the following standard having been adopted by the national Joint Committee on Definitions and Standards, is hereby established as the standard governing the production and sale of maple syrup within the State of New Hampshire:

"Maple syrup is syrup made by the evaporation of maple sap or by the solution of maple concrete, and contains not less than thirty-five per cent. of water and weighs not less than eleven pounds to the gallon."

Diet in Medicine.—An editorial writer in the *American Journal of Electrotherapeutics and Radiology*, for June, 1916, asserts that diet, more than any other factor, determines longevity. Establishment of correct dietetic habits in a child by the parent does more for its future health than heredity. In childhood, epilepsy, chorea, chronic nephritis, endocarditis, and arthritis are largely due to protein excesses, while in advanced years many are similarly victims to cardiovascular, renal, joint, or other diseases traceable to excessive eating. There is, therefore, no subject in medicine so important as teaching human beings how to live, especially in a land of plenty such as the United States. Blood pressure is in all ages an accurate index of intoxication from excess of food. A child under twelve years of age having a systolic blood pressure above eighty-five mm. Hg., or an adult at any age with a pressure above 120 mm., will as a rule be consuming an excess of poison-producing food, and a correction of diet is indicated when the pressure is above these figures. Thus the question of diet often becomes the most important of all from the viewpoint of both prevention and cure.

Nonirritation Treatment of Pyloric Ulcer.—J. W. Schuman (*Medical Herald*, May, 1916), with the object of continuously preventing the irritation caused by pyloric ulcer and thereby often leading to a medical cure, employs the following diet scheme: At 7 a. m. the patient receives a breakfast of fruit, cereal with cream, buttered toast, crisp bacon, and two glasses of milk and cream. Two hours later a glass of milk and cream with some graham or soda crackers should be taken. At noon the lunch should be taken as usual with the addition of buttered brown bread and two glasses of milk and cream. The 9 a. m. feeding should be repeated at 3 p. m. and at 6 p. m. regular dinner should be eaten, which should include some well buttered brown bread, green vegetables, fat meat, a potato, and two glasses of the milk and cream. The milk and cream should be taken again at 9:30 p. m. along with a bread and butter sandwich and at 1.30 a. m. the patient should be wakened to take another glass of milk and cream with some soda crackers. Eight to ten hours of sleep should be secured, and a good evacuation of the bowels each morning is essential. No fried foods, except crisp bacon should be allowed. It is not necessary for the patient to be kept in bed during the treatment. The régime must be kept up for several months without a break if cure is to be accomplished.

QUESTIONS EVERY MOTHER SHOULD ASK HERSELF.

At the end of *Farmer's Bulletin*, No. 717, issued by the Department of Agriculture, as a review, the author, Caroline L. Hunt, suggests that at the close of the day every mother might ask herself the following questions, to be sure that she has considered the important things in feeding her children:

Did each child take about a quart of milk in one form or another?

Have I taken pains to see that the milk that comes to my house has been handled in a clean way.

If I was obliged to serve skim milk for the sake of cleanness or economy, did I supply a little extra fat in some other way?

Were the fats which I gave the child of the wholesome kind found in milk, cream, butter, and salad oils, or of the unwholesome kind found in doughnuts and other fried foods?

Did I make good use of all skim milk by using it in the preparation of cereal mushes, puddings, or otherwise?

Were all cereal foods thoroughly cooked?

Was the bread soggy? If so, was it because the loaves were too large, or because they were not cooked long enough?

Did I take pains to get a variety of foods from the cereal group by serving a cereal mush once during the day?

Did I keep in mind that while cereals are good foods in themselves, they do not take the place of meat, milk, eggs, fruit, and vegetables?

Did I keep in mind that children who do not have plenty of fruit and vegetables need whole wheat bread and whole grains served in other ways?

Did each child have an egg or an equivalent amount of meat, fish, or poultry?

Did any child have more than this of flesh foods or eggs? If so, might the money not have been better spent for fruits or vegetables?

If I was unable to get milk, meat, fish, poultry, or eggs, did I serve dried beans, or other legumes thoroughly cooked and carefully seasoned?

Were vegetables and fruits both on the child's bill of fare once during the day? If not, was it because we have not taken pains to raise them in our home garden?

Did either the fruit or the vegetable disagree with the child? If so, ought I to have cooked it more thoroughly, chopped it more finely, or have removed the skins or seeds?

Was the child given sweets between meals, or anything that tempted him to eat when he was not hungry?

Was he allowed to eat sweets when he should have been drinking milk or eating cereals, meat, eggs, fruit, or vegetables?

Were the sweets given to the child simple, i. e., unmixed with much fat or with hard substances difficult to chew, and not highly flavored?

Was the food served in a neat and orderly way, and did the child take time to chew his food properly?

The Bluff Meal.—J. M. Bell (*Medical Herald*, May, 1916) points out that it is often necessary to restrict the amount of food taken in various conditions, such as those associated with plethora, heart disease, arteriosclerosis, nephritis, etc., and this is frequently a difficult matter owing to the resistance of the patient. A satisfactory and successful means of securing the desired restriction is by the prescription of the one hearty meal of the day so as to secure bulk without much food value. For this purpose the bluff meal may be ordered, consisting of: A first course of olives, radishes, or celery, and a strained meat soup; a second course of one ounce of smoked fish with an abundance of water cress and potato chips. The third course may contain stewed celery, stewed onions, asparagus, cranberries, parsnips, turnips, carrots, fried egg plant, cole slaw—none being prepared with milk. A salad of tomatoes, lettuce, or cucumbers with dressing may follow, and the final course should consist of gelatin in some form, tapioca, or fruit salad, nuts and raisins. One glass of cold water is allowed with the meal. Such a meal contains only 300 to 400 calories, but tastes well and gives a comfortable sense of fullness. The other meals of the day obviously should be restricted, but this one should be ordered without suggesting to the patient that it is of low food value.

Contemporary Comment

Thought and Action.—Say what you like, thinking is demoralizing, observes *Medical Times* for August, 1916, if you are a man of action, particularly a man concerned with things that you often have to do and which are vitally important. We mean, of course, that it is a bad thing to think about anything but the matter in hand. Take the surgeon; it is best that he be not so cultured and thoughtful as to be unable to keep his mind off a paper on Galen as surgeon to the gladiators when he is relieving a Lane's kink. Take the physician; it is best that he not think about the side chain theory when going over a chest.

Now there are those who think that the ideal physician is one who strikes a cultural balance and who is deeply interested in many things beside medicine. Unquestionably such a man is more human and attractive, but the man who has a passion for medicine alone is apt to be a better and a safer doctor, however much of a bore he may be outside of the sick room. In this discussion we are taking no account of the man who pretends to cultural veneer that deceives but few.

Upon the whole, the man who devotes the major part of his thoughts in repose to the work that he does in action, and who, when in action, thinks only about the particular job he happens to be doing, is a good man to employ.

Versatility is a great thing from an esthetic standpoint; but when one has an acute abdomen a thorough craftsman is needed; one doesn't care then how little the operator knows about Arabian medicine or old china.

Editorial Notes and Comments

NEW YORK MEDICAL JOURNAL
INCORPORATING THE
Philadelphia Medical Journal
and The Medical News.
A Weekly Review of Medicine.

EDITORS
